ORIGINAL COMMUNICATIONS.

CASE OF COMPOUND COMMINUTED FRACTURE OF THE SKULL,

INVOLVING THE LEFT TEMPORAL, SPHENOID, AND SUPERIOR MAXILLARY BONES; LACERATION OF THE BRAIN; PARALYSIS OF THE FIRST, SECOND, THIRD, FOURTH, FIFTH, SIXTH, AND SEVENTH CRANIAL NERVES; RECOVERY; WITH EXPERIMENTS UPON THE IRIS; DEATH THREE MONTHS AFTER THE INJURY, FROM ABSCESS OF THE BRAIN.—WITH REMARKS.

BY THOMAS G. MORTON, M.D.,

One of the Attending Surgeons to the Pennsylvania Hospital.

W. H., aged 47, was brought to the Pennsylvania Hospital as a "recent accident," late in the afternoon of the 24th of July, 1873. No reliable account of the case could be obtained at the time of his admission; but it was afterwards ascertained that the man had left Phoenixville on a coal-train the evening before, a collision occurred, and he was thrown from the train, and found some hours

afterwards in an unconscious state. On admission, the left temporal bone was found terribly comminuted, presenting an opening an inch and a half in diameter, with an extensively lacerated dura mater; numerous fragments of bone were removed from the brain itself. The fracture extended deeply into the petrous portion of the temporal bone, and apparently involved to a considerable extent the base of the cranium; large lacerations were found involving the ear and side of the head, and several teeth had been broken off. Profound coma was present during the succeeding ten days; when a gradual improvement was observed, and paralysis was found on the left side of the face. On being questioned concerning the accident, his answers were variable and quite unsatisfactory. Very great swelling of the face continued for a fortnight or so, and then slowly subsided. The wound suppurated freely, without any disposition to fungus of the brain; the centre of the cornea showed a superficial abrasion. The conjunctiva from the first was congested and markedly oedematous, and the pupil considerably dilated.

FIG. 1.

FIG. 2.

August 30.—There is complete facial palsy on the left side (Fig. 1). The wound has almost closed up. A fistulous track extends from the external ear inwards and forwards; a probe passed in joins a fistulous track from the main wound, and passes directly forward and inward some two inches (Fig. 2). The general condition of the patient is excellent; headache has been a marked symptom, but of late has been considerably less. He walks about as usual, going to and from the hospital; has some difficulty in masticating and swallowing his food; his intellect is probably as clear as before the accident.

September 3.—Examination made in the presence

of Drs. William Hunt, H. C. Wood, and others. The cranial nerve-distribution on the right side is normal. On the left side, the first, second, third, fourth, fifth, sixth, seventh, and possibly the ninth nerves are palsied. Irritants and odorous substances, cologne, vinegar, and ammonia, when applied to the left nostril are not perceived. The left eye is stone-blind, is absolutely motionless, and totally devoid of sensibility. The mucous membrane of the lids is also insensitive. The pupil is moderately and regularly dilated, measures one-fifth of an inch in diameter, and does not respond to light. The optic papilla presents white atrophy.

The conjunctiva is passively congested, and slightly œdematous. The cornea is normal, except a superficial central opacity; the lachrymal secretion is slight, and not increased in the least by irritants applied to the conjunctiva. The globe of the eye projects half an inch beyond the right; there is complete ptosis. Anæsthesia exists over the face and brow; sensation exists on the outer edge of the upper eyelid and on the skin of the temple and ear; the muscles of the left side of the face are palsied; the auditory nerve is susceptible of impressions, but these are very imperfectly conducted. There is loss of taste on the left side of the tongue, and absence of sensation of the mucous membrane of this side of the mouth, fauces, tongue, and palate. The line of skin-anæsthesia is measured from a trifle within the median line on the left side of the face, extending along the nose to the upper lip, and outward two inches beyond the corner of the mouth, then upward to a point near the angle of the eye, where sensation exists. The anæsthesia in the brow corresponds to the distribution of the supra-orbital nerve. The cornea has been very superficially abraded in the centre; the conjunctiva when examined two days after the accident was found very much congested, and this condition remains to the present time, with slight œdema. To test the absence of lachrymal secretion, the upper eyelid was securely held open for an hour, at the end of which time the conjunctiva and globe of the eye were intensely congested, and of a purplish-red color. The cornea and conjunctiva were absolutely dry, and it was deemed prudent not to continue the exposure any longer, for fear of permanent injury.

The right eye showed normal acuity of vision, with a presbyopia = $\frac{1}{24}$; but the field of vision is much contracted (Fig. 3).

FIG. 3.

EXPERIMENTS UPON THE PALSIED EYE.

September 4.—The eyeball is absolutely motionless and insensitive; the pupil one-fifth of an inch in diameter; no effect is produced on the iris by light. A solution of atropia, gr. ij to f3i, applied. In ten minutes the pupil measured one-fourth of an inch, and is regularly dilated.

September 9.—Extract of Calabar bean applied to the conjunctiva; the pupil one-fifth of an inch in diameter; in half an hour the pupil contracted to one-twentieth of an inch.

September 13.—The contracted condition continued for two days, and gradually passed away; the pupil has resumed its dilatation of one-fifth of an inch.

September 20.—Pupil one-fifth of an inch. One-fourth of a grain of atropia was injected into the patient's arm, with no effect upon either pupil.

September 22.—One-thirtieth of a grain of atropia was injected, with no effect upon either eye; no constitutional symptoms.

September 23.—The right pupil measured one-eighth, the left one-fifth of an inch. One-twentieth of a grain of atropia was injected; in fifteen minutes there was some dryness of the throat, with unsteadiness in walking, dilatation of the pupil of the left eye, and very appreciable enlargement of the right pupil. In three hours the right pupil measured three-sixteenths, the left one-fourth of an inch.

October 1.—During the past few days intense and continued pain in the head has been noticed, and for the first time since the injury a slight movement is observed in the left eyeball, only, however, when the sound eye is moved; there is also some sensation on the outer part of the upper eyelid.

October 8.—Within the past forty-eight hours the patient has had increased pain, intense on the left side of the head; a sudden œdema of the conjunctiva of the lower eyelid has produced excessive ectropion, and, on account of this, the cornea, being exposed at its lower border, presents an extensive cloudiness with a tendency to slough. The lids were accurately approximated with adhesive plaster.

October 10.—The cornea is resuming its normal appearance, and all disposition to further slough has disappeared. The patient has been confined to bed for several days past, on account of intense pain and general prostration.

October 12.—There is scarcely any discharge from the place of original injury.

October 13.—The right pupil measures one-sixteenth of an inch; the left pupil measures one-sixth of an inch.

The cornea is again quite clear; the finger passed over the abraded spot removed all the slough and left the cornea normal.*

From October 13 the patient suffered terribly with cephalalgia, and had little or no disposition to be out of his bed. His appetite became impaired, and finally stupor and coma supervened. For six days he was in a dying condition, unable to articu-

* There is at present in the Pennsylvania Hospital a young man who received a blow at the root of the nose by a bar of iron; he was quite insensible for several days; he is now (October 1) stone-blind in the left eye from the injury; the size of the pupil varies accurately with that of the sound eye; when the sound eye is closed the pupil of the blind eye is dilated; the most powerful light does not produce the least response; the iris remains widely dilated; light admitted to the sound eye produces active contraction of the iris of the blind eye.

November 15, a negro woman was admitted into the Wills Hospital with paralysis of the second, third, fourth, ophthalmic branch of the fifth and sixth cranial nerves on the right side. The eyeball is motionless and insensitive, with ptosis; the pupil dilated, the media of the eye clear, with white atrophy of the optic disk. A solution of atropia in ten minutes produced a great dilatation; and Calabar bean contracted the pupil. The cornea is completely covered by the lid, and remains normal; the secretion of tears is very slight.

late or swallow, with a pulse of 150 and a very rapid respiration. Death occurred October 22, ninety-one days after the receipt of the injury.

Post-mortem.—On removing the calvarium, there was considerable venous congestion of the dura mater and pia mater; lymph attachments glued the brain and membranes firmly along the region of fracture; the anterior portion of the middle lobe of the brain was found softened and wasted, and on pressing it aside a quantity of purulent matter escaped; on slicing off the cerebrum a large abscess was found which involved the entire extent of the left middle lobe, the fissure of Sylvius, and to a considerable extent the anterior lobe; and the left lateral ventricles were full of pus in all their horns. The abscess involved the origin of the left olfactory, which showed no adhesion to the cribriform plate, and the filaments of the nerve were absent, the optic tract, crus cerebri, origins of the third and fourth nerves; the fifth and sixth nerves were also involved as they passed along to their places of emergence; the nerves which passed through the sphenoidal fissure, foramen rotundum, oval and spinous foramina, were softened, being directly in the line of the abscess and fracture. The left optic nerve was softened from a point commencing half an inch in front of the chiasm; the choroid plexus was covered with layers of thick lymph; the tubercula quadrigemina and ventriculus tertius were normal. A probe could be introduced into the left ear an inch and a half; into the original wound a probe could be passed downwards and forwards an inch and a half, coming in contact with denuded bone. Opposite the anterior portion of the middle lobe, where the skull had been fractured, a portion of bone had been driven in, and had united at an angle which produced an encroachment upon the space designed for the middle lobe. The line of fracture commences at the meatus auditorius externus, and involves the anterior third of this bony canal and extends through the petrous portion of the temporal bone, dividing it into two nearly equal portions, sweeping away the anterior portion of the carotid canal, then extends to the body of the sphenoid bone, and involves the posterior clinoid process, along the sella turcica, breaking off one-fourth of the body of the sphenoid bone; on the left side of the sella turcica an opening one-fourth of an inch in length and one-twelfth of an inch in breadth is observed, the result of a comminution at the time of injury. The fracture extends to the lesser wing of the sphenoid and into the optic foramen, then to the sphenoidal fissure, the orbital surface of the palate bone, the great wing of the sphenoid, post-orbital edge of the malar bone, extending upwards into the squamous portion of the temporal bone, along the temporal ridge in a curved direction, upwards, downwards, and backwards, to the upper surface of the external auditory meatus. The zygoma, with a portion of the external angular portion of the malar bone, which was separated from the frontal, is absent. All that portion of bone included in the above area described as the line of fracture—namely, the base of the skull, together with the styloid process of the temporal bone and the glenoid fissure—has been en-

tirely separated from its original location, and driven downwards and inwards, and is firmly united angularly one inch below its normal position. All the nerves passing through the oval, round, sphenoid, optic, and stylo-mastoid foramina were involved in the line of fracture, were softened and firmly matted together, and surrounded by pus. The pterygoid process on the left side had been fractured at its base, and irregular union has occurred.

Remarks.—It is remarkable that with such a severe brain-injury, and involving such an extent of the base of the skull, and the destruction of so many of the cranial nerves, the patient should have lived, and presenting such fair prospects, for a time, of ultimate recovery. The results obtained from the injections of atropine are in accordance with those of experiments upon animals. The work of the physiologist has rendered it almost certain (see H. C. Wood's "Therapeutics," p. 220) that when atropia is given internally the iris is dilated, not by an action exerted upon the nervous centres, but by a direct influence upon the iris itself, to which the blood carries the alkaloid. In the present instance all the connections of the iris with the nerve-centres were involved, yet atropia, given hypodermically, dilated the pupil,—not so quickly, it is true, as it did that of the uninjured eye, but yet very decidedly. It must be remembered that the accident which severed the nerves of the eye also in great measure cut off the blood-supply of the organ, only barely enough blood finding its way into it to maintain its life. The sound eye, therefore, received a much larger dose of the poison, which was dissolved in the blood, and, of course, manifested more rapidly its influence.

REPORT OF CLINICAL CASES OF DISEASES OF THE EAR, THE CHIEF SYMPTOMS OF WHICH WERE "TINNITUS AURIUM," OR NOISES IN THE EARS.

ILLUSTRATIVE OF A PAPER PUBLISHED IN THE "PHILADELPHIA MEDICAL TIMES," JUNE 27, 1874.

BY LAURENCE TURNBULL, M.D.,

Physician to the Department of Diseases of Eye and Ear, Howard Hospital, Philadelphia.

CASE I.—Tinnitus. The sounds resembling the action of a pump and the hissing of a snake, the result of impacted cerumen and the excessive use of tobacco.

Henry L., aged 30, residence Philadelphia, occupation painter, complained of deafness, with sounds like the hissing of a snake and the action of a pump. The patient uses tobacco to excess, both smoking and chewing. He is so deaf in the right ear that a loud-ticking watch is only heard in close contact. Left ear almost normal in hearing. On examination of right ear the meatus is found covered with patches of altered cerumen, while the membrana tympani is entirely covered with a concave mass, as if melted by heat. There is not much doubt that by its pressure it first displaced and caused absorption of the air in the middle ear, driving the malleus inwards and pressing the stapes into the fenestra ovalis. Directed a warm solution of bicarbonate of soda, in equal parts of glycerin and water, to be dropped into the meatus warm for three nights,

and on the morning of the fourth day the parts were washed out by means of the syringe. This procedure did not give entire relief until fresh warm air was blown in by Politzer's apparatus, when the concave membrane assumed its normal character, and the deafness and sound disappeared.

Case II.—Fluttering tinnitus with deafness of one ear, since June, 1873; the result of bathing. Treatment for two weeks with almost entire relief.

Oliver W. L., aged 14, student, Berks county, Pa., sent by Dr. E. B. Shapleigh, of Philadelphia. General health good, pulse rapid, no valvular murmur, no enlargement of heart; has constant fluttering noise in left ear; never free, night or day. Mother deaf in both ears, from cold; no other member of the family deaf. Deafness and noises commenced in June, 1873; no discharge, no pain. Left ear—hearing-distance, $\frac{3}{8}$; right, $\frac{3}{8}$. No disease of auditory canal or membrana tympani. Right Eustachian tube open and free; left contained inspissated mucus. The naso-pharyngeal mucous membrane swollen, and considerable discharge from it. Treatment prior to coming under the writer's care, washing out ear, applying counter-irritation, oils, etc., but with no benefit. Treatment first two days, inflated the middle ear; slight relief. Finding the mucus tough and somewhat dry, resorted to Lucca's plan of injecting a few drops of a solution of chloral hydrate (10 to 30 grains) to $\frac{f}{3}$ of tepid water into the middle ear by means of the Eustachian catheter. This was disagreeable, but not painful; after ten applications, as the results did not afford permanent relief, omitted it, and employed the nasal douche with warm solution of common salt, alternated with solution of zinci sulphas in water, to wash out any accumulation in the naso-pharyngeal space. This relieved him, but only temporarily, and was continued for four days, followed by the use of the galvano-magnetic current, applied by the author's modification of the rheophore of Duchenne. The insulated conductor was passed near to the membrana tympani through a warm solution of chloride of sodium. This gave him considerable pain, but entire relief from the noises, with improved hearing in the left ear, so that he was able to resume his studies.

Case III.—Tinnitus the result of chronic catarrh, with depressed membrana tympani (deafness).

H. G. H., aged 40, native of Pennsylvania; merchant, doing business in Philadelphia; has suffered from constant noises in the left ear, with deafness to low sounds, for years. General health impaired, loss of appetite, and much depression. Applied to the writer December 25, 1873, being recommended by Dr. Lewis of this city.

History: frequent attacks of cold in the head; employed tobacco, and had all the symptoms of follicular pharyngitis; with nasal catarrh, using a number of handkerchiefs each day, and expectorating disgusting masses of altered mucus, which was hardened, and in some instances tinged with blood. The left Eustachian tube was narrowed and diminished in its power of opening during deglutition, and the hearing in the left ear to $\frac{1}{8}$; in the right the hearing was $\frac{3}{8}$, and the tube more free. In the right membrana tympani there was subacute inflammation, and handle of malleus injected, with short process very prominent and membrane sunken. Left, no symptoms of inflammation, but deeply-sunken membrane.

Prior to his coming under the writer's care, this gentleman had been under the treatment of almost every quack in this city, and had spent a large sum of money without benefit. He had also been treated by a number of able medical gentlemen, regular members of the profession.

The treatment of the throat, pharynx, etc., was continued until the patient ceased to have the constant discharge. The sunken membrana tympani was elevated by means of Siegle's aural speculum, and the middle ear was medicated with various solutions, restoring it to a more healthy condition. It was still found that the sounds were moderated, but no definite change in the "tinnitus."

May 8, 1874, performed tenotomy of the tensor tympani after Weber's method, and placed the patient on the use of a mixture of spiritus terebinthinæ; this was followed by no great change in the sounds. On the 12th, injected through the opening, which had not closed, a warm solution of sulphate of zinc, gr. iij to $\frac{f}{3}$ of water. This was done by fitting the nozzle of the syringe to the meatus by means of an extra india-rubber packing. The syringe was very carefully and gradually employed, until the fluid passed by the nostril. This was followed by a dull, heavy pain, and the patient felt faint; relieved by the application of the air-douche, one-fourth grain of morphia by the mouth, and the inhalation of chloroform. He complained also of a crackling like the breaking of bubbles of air; still no permanent relief of the noises, which he likened to those of a boiling tea-kettle.

Faradization was then tried; for several weeks he had the fly-like noise in the ear, but when the application was withdrawn he was no better.

Having tried all the ordinary means of relief, and the throat being improved, middle ear free, membrana tympani raised, I placed the patient upon a supporting and stimulating treatment for his brain, by the use of diluted phosphoric acid, with iron, with decided benefit, while I simply kept the orifice of the Eustachian tube free from mucus by the posterior nasal syringe and solution of common salt. To correct the fulness of his head and constipation, I directed Oak Orchard salts, a mild saline aperient. This latter treatment he has been under, and he feels freer from the noises, is in better spirits, and is now able to say that he feels better than he has felt for years.

During my absence this summer, 1874, he visited my friend Dr. Cohen by my request, who tried the constant current with much the same results as those obtained by faradization, so that he fell back upon the same treatment under which I had placed him.

Case IV.—Tinnitus the result of collapse of the Eustachian tube, without deafness.

B. N. B., M.D., aged 34 years, residence Philadelphia, applied April 7, 1874, to the writer, suffering with a buzzing noise in the right ear. This was of four months' duration, and the blowing sound increasing as if into a bottle. It disturbed his sleep, and he was unable to perform his duties with comfort or satisfaction. He had consulted four physicians, and, having some sore throat, all the remedies were applied to it.

On examination, found the hearing of both sides normal, membrana tympani of the right slightly drawn inwards, but no prominence of the handle of the malleus, with no opacity of the membrana tympani. The left Eustachian tube was free, and air passed into the middle ear without any difficulty. The right was found obstructed in the pharyngeal orifice, which the writer endeavored to overcome by the use of the air-douche and Eustachian catheter, which were followed by slight improvement. A few days after, a Eustachian bougie was introduced by the aid of the rhinoscopic mirror, and an application made to the orifice of the tube, of equal parts of diluted carbolic acid and tincture of iodine. This treatment was continued, and removed every trace of the noises. The bougie was a metallic one, acutely curved, introduced by the mouth, and its use was to stimulate the mucous membrane

lining the tube, and thus remove the collapse and swelling. This bougie was introduced only into the wide portion of the tube. These bougies are employed from No. 2 to No. 5 of the French scale, and it is well to remember that the distance from the widest portion of the mouth to the isthmus or narrowest part of the tube is seventy-four millimetres, and the distance from the point to the tympanic cavity eleven millimetres, and the width of the cavity thirteen millimetres.

Another case of much the same character came under the writer's notice, but the results were not so satisfactory, owing to the length of time which elapsed before the patient applied for relief. It was as follows:

Case V.—Isabella V., aged 25, resident of Philadelphia, a lady of education, and very intelligent, applied May, 1874, stating that she was suffering with a constant buzzing sound without deafness; thought it was due to the result of a very severe cold; no pain. On examination of the offending ear, which was the right, found her hearing was $\frac{1}{2}$ left, right $\frac{1}{3}$, showing an amount of deafness by the watch which was not noticed in hearing the human voice. In the right meatus there was an excess of cerumen, the removal of which improved that ear to $\frac{2}{3}$. The right membrana tympani was found normal. Left membrana tympani sunken, and Eustachian tube of left side closed by a dark mass when it was examined by the rhinoscopic mirror. This was removed by the nasal douche, and the iodine and carbolic acid applied to the ulcer which was found under it. A strong solution of common salt alternating with a solution of sulphate of zinc was then directed to be employed at home.

May 22.—Returned and expressed her thanks for the relief afforded; she was so much improved as to be able to sleep, and was almost free from the tinnitus unless much excited. She had been under the care of an aural surgeon of this city for three months, who had employed a large Politzer's air-douche at each visit, and the application of the constant current to the ears, which, she stated, instead of improving her had only increased her distress.

(To be continued.)

NOTES OF HOSPITAL PRACTICE.

ST. MARY'S HOSPITAL.

SERVICE OF DR. F. EWING MEARS.

COMPOUND COMMUNUTED FRACTURE OF THE SKULL,
INVOLVING BOTH TABLES, WITH DEPRESSION.

WILLIAM McD., æt. 14, was admitted into the surgical wards of the hospital, August 19, suffering from a wound of the cranium. It was stated that he had sustained the injury at Cramp's shipyard; an iron clamp or dog weighing fourteen pounds falling a distance of thirty feet, his head being struck by the angle of the tool. He was stunned by the blow, but soon regained consciousness, and when admitted he was able to give an account of the injury. Examination revealed a lacerated wound of the scalp over the frontal bone, about one inch from the line indicating the position of the frontal suture. On separating the flaps the bone was found depressed to the extent of half an inch, and the external table was very much comminuted. Nausea and vomiting were present, the pupils were largely dilated, the pulse slow and full, and respiration was somewhat labored.

Although the symptoms of compression were not strongly marked, Dr. Mears deemed it advisable, in view of the character of the wound, to remove the fragments of bone, and thus avoid the possible dangers of

subsequent compression or the occurrence of intracranial suppuration.

Owing to the size of the wound of the bone, it was impossible to apply the trephine. After enlarging the wound of the scalp by incisions, the elevator was applied, and the comminuted portions of the outer table, some eighteen in number, were detached. After removing these it was found that the inner table had been pushed off, as it were, *en masse*, leaving a loose fragment much larger in diameter than the opening in the outer table. This fragment, after numerous attempts, was sufficiently dislodged (being pushed aside) to admit of its division by the bone-pliers. The portions were then readily extracted, and the dura mater brought into view; with the exception of a wound of one of the small arteries of this membrane, the hemorrhage from which was easily checked, it was uninjured. The wound was well cleansed by gently injecting cold water, and the incisions in the scalp were closed by wire sutures. The wound was strapped with isinglass-plaster, and covered by compresses wet with ice-water. The head was kept elevated; as soon as the patient recovered from the effects of the anæsthetics, a drop of croton oil was administered. This failing to produce any effect, eight grains of calomel were given, which soon opened the bowels freely. Instructions were given to keep him perfectly quiet, and to continue cold applications to the head; one grain of calomel three times daily was administered. Sloughing of the portion of lacerated scalp occurred, and the dead tissue was removed by the scissors. Healthy suppuration soon took place, and the wound was rapidly filled by granulations.

September 17.—The wound is closed, with the exception of a slight surface about the size of the nail of the little finger. A large depression is left on the surface. The recovery of the patient has been uninterrupted.

Remarks.—At first view this wound appeared to partake largely of the character of an impacted fracture, and, as such, it was a question not readily decided as to the propriety of operative interference. The symptoms of compression also, as has been stated, were not strongly marked.

The depressed character of the wound produced apprehensions as to the subsequent effects, and seemed to justify the removal of the fragments. The fact that the inner table was found to be detached to so large an extent, and that there existed a wound of one of the vessels of the dura mater which poured out a quantity of blood, fully confirmed the propriety of removing the bone. The measurements of the fragment from the inner table were found to be in the long diameter two inches, in the short diameter $1\frac{1}{2}$ inches; of the external plate in the long diameter $1\frac{1}{4}$ inches, in the short diameter $1\frac{1}{2}$ inches.

The fracture involved the frontal bone, situated about one inch from the line indicating the position of the obliterated frontal suture, and was limited behind by the coronal suture.

EXTENSIVE WOUND OF THE SKULL, PRODUCED BY A
CIRCULAR SAW.

A. B., æt. 18, was admitted August 21, with an extensive wound of the skull, which was produced in the following way. The patient was engaged in collecting saw-dust in a basket, and for this purpose had crawled under a bench connected with which was a circular saw. The attendant, unaware of the presence of the man beneath the bench, suddenly set the saw in motion, which struck his head; the saw entered first at the junction of the middle and outer third of the right supra-orbital ridge, cutting obliquely across the vertex through the coronal suture, the right parietal bone, the sagittal suture, and terminating in the left parietal bone, about one inch from the sagittal suture. The length of

the wound made by the saw was seven and three-quarter inches, the width one-third of an inch; the depth of the wound through bone and in the brain-substance was four inches, according to the most accurate measurements which could be made in the absence of a post-mortem examination, which was not permitted. The edges of the wound in the bone were rough and uneven, and the brain-substance appeared to be somewhat lacerated by the large teeth of the saw. At the time of admission—three-quarters of an hour after the receipt of the injury—the patient was conscious, and struggled violently with those who had him in charge. Profuse hemorrhage had occurred, and continued after his admission. He complained of severe pain in his head, on the side of the wound, and desired to lie on that side. There was no paralysis and no convulsive movements. He died about an hour after admission, from exhaustion. As above stated, no post-mortem examination was permitted, by which alone could have been determined the exact extent of injury to the brain. The absence of any marked symptoms indicating lesion of the nerve-centres would imply that the saw passed only through the cortical substance of the brain. Neither the special senses, common sensation, nor motion were impaired. The patient appeared acutely sensible of the severe pain caused by the wound. The active movements made by the patient were in decided contrast to the symptoms usually manifested in cases of traumatic lesions of the brain, and attracted attention.

TRANSLATIONS.

A PECULIAR AFFECTION OF THE FINGERS (Dr. Arthur Menzel: *Centralblatt für Chirurgie*, No. 22, 1874).—A peculiar, incomplete stiffness of the fingers was described by Notha and Nélaton, in which the fingers, in other respects normal, resisted for some time all attempts to flex or extend them, and then suddenly yielded, their motion being attended by pain and a snapping sound like that caused by closing the blade of a pocket-knife. Nélaton thought that this affection was caused by the existence of a hard, round, movable body, of the size of a lentil, in the flexor tendons. When an attempt was made to flex the finger, the rolling body met with a resistance from the fibrous bands which strengthen the sheaths of the tendons; but if the effort was continued, and force enough used, the body forced its way through these bands and sprang forward upon the other side of them. W. Busch (*Handbuch der Chirurgie*) has observed two cases of this affection, but was unable to discover anything abnormal either in the joints or in the sheaths of the tendons. Prof. Pitka (*Pitka-Billroth Chirur.*) has no acquaintance with cases of this kind from personal observation, but thinks that the most probable explanation is that they are due to a movable cartilage in the joint. Hyrtl also has never seen a case, but thinks "that, on theoretical grounds, this curious condition can only be due to a circumscribed thickening on one or the other of the flexor tendons, with a simultaneous limited contraction of a certain portion of the sheath of the tendon." Finally, Dr. Hahn has described an interesting case in which the affection was symmetrical, both ring-fingers being involved. In this case the first interphalangeal articulation of both ring-fingers cracked, while the most painful points were found to be on the flexor aspect of the fingers corresponding to the metacarpophalangeal articulations, and from the flexor tendon at this point there could be felt a rather hard, immovable projection which was especially painful.

Dr. Menzel adds to those already recorded the history of one more case, which he considers interesting in itself, and which he hopes may facilitate the explanation of the cause of this singular phenomenon.

M. F., aged 42, a woman whose occupation was embroidering, suffered during the past winter from rheumatic pains in the lower extremities. On the 16th of May of this year, while she was at her work, she suddenly had such a severe pain in the metacarpophalangeal articulation of the right thumb that she was forced to cry out. She thought that she had thrust a needle or a thorn into her flesh, but, by a careful examination, satisfied herself that this had not been the case. From this time the pain was never entirely absent, either by day or by night. After the expiration of two weeks she first noticed the cracking of the thumb upon flexion, and sometimes she was not able to bend it at all. When Dr. M. first examined the case, on the 16th of July, he found the following: As soon as the last phalanx of the right thumb was bent to an angle of one hundred and fifty degrees, a resistance was experienced, but if flexion was continued with a moderate increase of force, the last phalanx suddenly sprang, with a moderate crack, to an angle of ninety degrees with the first phalanx. The same phenomena were noticed when the finger was extended from the flexed position, and they occurred whether the motions were of an active or passive character. Both the patient and those who examined her placed the springing and cracking in the interphalangeal articulation, but the most careful examination failed to discover anything abnormal in this joint. On the other hand, a point was found upon the flexor tendon corresponding to the metacarpophalangeal articulation which was extremely painful upon pressure, and upon the ulnar side of this same point was a hard, immovable body of the size of a lentil, which seemed to be the source whence all the pain started. On the corresponding part of the thumb of the other hand there was a projection similar in all respects to the one upon the right side except in the entire absence of pain.

This case is worthy of special observation, since the affection was apparently situated in the interphalangeal articulation, while the excessive pain on the volar aspect of the metacarpophalangeal joint rendered it highly probable that the cause of the singular condition was some change in the tendon and its sheath. Dr. M. and his assistant then made some experiments upon the cadaver in an endeavor to ascertain if a tumor in the tendon due to thickening would be sufficient to cause these phenomena in a finger. Since the tendinous sheaths are provided with numerous tense, fibrous bands in order to strengthen them, it might be possible that the sudden overcoming of such bands by a tumor in the tendon would occasion the springing of the finger. The tendon of the flexor profundus was exposed and raised, and a string was tied tightly around it from two to four times. These repeated turns of the thread made a projection which represented a small circumscribed tumor of the tendon. The tendon was then replaced in its sheath, and flexion was made either by force applied to the finger itself or by traction exercised on the tendon over the wrist. The motions of the finger thus prepared were not so free as those which were uninjured, but nothing approaching the condition described as existing in the patient was obtained. This first occurred when, in addition to the tumor of the tendon, the resistance of its sheath at an appropriate place was considerably increased or diminished. In order to increase this resistance, an artificial constriction of the sheath was effected by a ligature firmly applied. The movement of the finger was now perfect until the tumor of the tendon reached the constricted portion of the sheath, when there was a cessation of

motion. If now the force was somewhat increased, the finger suddenly sprang into the wished-for position, and this movement was attended by a snap. The sensation which was transmitted to the operator gave the idea that the lesion was within the joint; indeed, the whole process was similar in every respect to that which took place in the patient and of which an account has just been given. Instead of making the constriction directly in the sheath, an experiment was tried with the constricting band around the uninjured skin of the finger; but this was not successful, for the tumor on the tendon passed through without causing the sudden spring of the phalanx which is so characteristic of the affection under discussion. If a small piece of the sheath of the tendon was removed, so that its power of resistance was diminished, the same phenomena were caused as when a constricting band was placed about the sheath. If the artificial tumor on the tendon was relatively large, more force was needed to force it through the sheath. If now the application of this force suddenly ceased, the tumor sprang to some distance, while there was an impression conveyed to the finger that the operation had taken place within the interphalangeal joint.

In order to test the truth of the theory of Nélaton in regard to the cause of this affection of the fingers, small grains of various kinds were introduced into the sheath and, by means of a fine probe, thrust forward some distance. These bodies most commonly arranged themselves on either side of the tendon, took but little if any part in its motions, and never gave rise to the condition of affairs which is under consideration. Dr. M. thinks that he can justly draw the following conclusions:

1. It is possible that the springing of the finger may be always due to an affection of the tendinous sheath; the observer, however, receives the phenomena as attributable to some condition of the joint.

2. Neither a tumor in the sinew nor a constriction of the sheath of the tendon of itself suffices for the production of the condition; both these conjoined are required.

3. The springing occurs also when, in addition to a tumor of the sinew, there is a tear of the sheath at a corresponding point.

4. Free bodies in the tendon will not produce this effect even when there is also constriction of the sheath; the tumor must be a part of the tendon itself. It is probable that the enlargement in the tendon and the constriction of its sheath are both the products of inflammation. In regard to the case detailed above, it can be stated that the peculiar condition disappeared in a few days by the use of tincture of iodine and warm baths; but motion remains painful, and the thumb cannot yet be used. It seemed to be of importance to ascertain the nature of the disease, and if it can be shown to be due to inflammatory deposits from a circumscribed chronic tendovaginitis, it will be no matter for wonder that the course of the affection is very tedious. The hard, oval, painful body at the side of the tendon opposite the metacarpophalangeal articulation corresponds to the free edge of the bony groove in the first phalanx of the thumb, in which lies the flexor tendon. Both of these edges, as a rule, are rather more projecting at this point. Between these bony edges a dense oblique projection is formed by the attachment of the capsular ligament of the metacarpophalangeal joint. It may be that this position, on account of the depth of the groove and the oblique projection of the attachment of the ligament, is especially predisposed to be the seat of contraction of the sheaths of the flexor tendons.

W. A.

THE DIURETIC ACTION OF DIGITALIS (Brunton and Power: *Centralblatt für die Med. Wissenschaften*, 1874,

No. 32).—Max. Hermann and Ludwig have shown that the rapidity with which the urine is secreted depends upon the difference between the pressure of the blood in the renal glomerules and that of the urine in the uriniferous tubules. At present it is supposed that the diuretic action of digitalis is not due to any specific property which it possesses, but to the power which it has of increasing the blood-pressure in the arterial system. The results of experiments which these observers made about a year ago show that this is not the case. After the injection of a considerable dose of digitalin into the veins of a dog into whose bladder a catheter had been introduced, the secretion was either suppressed or at least considerably diminished, while the blood-pressure was simultaneously increased. Some time later, the pressure fell, and in some of the experiments the secretion of urine reappeared with the sinking of the blood-pressure, while in others no reappearance of the secretion took place until the pressure had become less than normal. In some cases the urine flowed more rapidly than in others, although the pressure was much below the normal standard. If the diuretic effect of digitalis is due entirely to the power which it has of increasing the blood-pressure, the flow of urine ought to be much increased immediately after the injection, and should also be diminished as the pressure falls. Instead of this, it was found that the secretion was least when the pressure was highest and became more plentiful when the blood-pressure had become less than normal. In explanation of these conditions it seems reasonable to suppose that digitalis has an irritative action upon the vaso-motor nervous system, and that its action in that respect is especially well marked upon the vaso-motor nerves of the kidney. It must at the same time be supposed that it gives rise to a moderate contraction of the vessels of the general circulation, and an increase of the blood-pressure in them, while in the kidneys it causes a higher degree of contraction of the arteries, in consequence of which there is an immediate cessation of the flow of the urine. As the irritant action on the vaso-motor nerves becomes less, and finally passes away, the renal vessels become flaccid more quickly and more completely than the others, so that the blood-pressure in the renal glomerules is still above its normal amount, although the tension of the vessels of the general circulation is below its average quantity. This supposition is further supported by the fact that the urine which is collected after the reappearance of the secretion contains albumen. This substance was found by Hermann after the circulation in the renal arteries was obstructed. The possibility that the variations of the secretion are partially dependent upon the direct influence of the medicine on the secreting elements of the kidney must not be overlooked, and these same experimenters are now investigating this point, and will in due time publish the results of their work.

EXPERIMENTS ON WHITE MICE WITH CHOLERA DEJECTIONS.—H. Ranke (*Bayerisch. Aerts. Intelligenz-Blatt*, 1874, No. 15) has repeated the experiments upon white mice with cholera dejections which were made by Thiersch twenty years ago. The earlier experiments were made by giving the animals infected paper, but in those of Ranke the dejections of cholera were mixed with milk which was then given to the mice. In two series of experiments he attained negative results. In accordance with the advice of V. Pettenkofer, he repeated the experiments in the dead-house of a hospital which contained cholera-patients, but here too the animals remained free from infection. When the mice were fed with uninfected filtering-paper, smeared with fat, they died without any apparent cause, and in their intestines were found gray, pulpy masses.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, OCTOBER 3, 1874.

EDITORIAL.

DR. HAMMOND'S DEFENCE.

DR. HAMMOND has published, in the *New York Medical Journal* for September, a very elaborate defence of his action in regard to the McCormick case. The line of defence is that there are certain subjects connected with medicine in which the public are especially interested, and upon which they desire information; and, further, that men of excellent standing in the New York and even in the Philadelphia profession have frequently gratified this desire of the laity for knowledge.

All of this is true, and certainly Dr. Hammond clears himself of any imputation of being a pioneer in this business. But we think it will hardly be judged otherwise than that he has gone farther than his predecessors, and has approached more closely the "dead-line" that separates quackery from regular medicine. Offence may be given by the manner as well as the matter of the doing, and it is difficult to conceive of anything more sensational than was the flurry about hydrophobia.

A revolution in professional ethics, as we have stated before this, seems to us imminent, simply from the fact that there is an inevitable tendency for each individual to step a little in front of his fellows and so to widen steadily the distance between the old and the present customs.

The splendid pecuniary success which Dr. Hammond claims to have attained, and of which he shows many tangible proofs, undoubtedly tempts men to follow his methods, and exerts an enormous

influence,—an influence which must be considered in at least some respects baneful by all those who revere the traditions of the fathers. We ourselves are tempted to believe that it would be fairer to the more scrupulous of the profession to abolish the Code of Ethics entirely than to let things drift as at present, and thus allow the use of well-tried business methods for success to those who are reckless of any professional public opinion which has not a dollars-and-cents value. As showing how the current is setting, we may mention the insertion, a few weeks since, by a "quiz organization" of a prominent medical college, of an advertisement in one of the evening penny papers. It was at a time when scarcely a student was in town, and the advertisement was in a paper that very few students in the city, certainly none out of it, see, and therefore could not possibly have availed in obtaining any students for the coming winter session. But then the names of the quizzers were in displayed type, each with his specialty set forth, and were scattered over the city among the very classes of the laity to be reached by such means. The kernel of the nut is not, we think, hard to discover. Even the defence of Dr. Hammond may serve as a sign-post of the times, if indeed it could with truth be granted that he has only done as do his professional brethren. How different in tone from Dr. Hammond's defence—which says in substance, "I allowed it; I furnished the wood-cuts to the newspapers; but the rest of you do the same thing"—is the recent indignant disavowal by Prof. Paget of any collusion with the publication of one of his lectures in the *Pictorial World*!—a disavowal in which he declares that he did all he could to prevent the publication, and adds, "I venture to hope that I am not thought likely to be guilty of encouraging the appearance of my name in newspapers."

Is further comment needed? Will libel suits and indulging in the school-boy wit of calling editors names render the difference between these two courses less apparent?

As most of our readers probably know, Dr. Hammond has sued the *New York Medical Record* for a libel, said to be contained in its editorial on the McCormick case. Of all the various public acts of Dr. Hammond during his eventful career of surgeon-general, physiologist, novelist, journalist, medical expert, professor, and practitioner, we know of none, not even the famous anti-calomel or tartar-emetic order, which is more novel, or to our thinking more uncalled for and injudicious. If professional men are not to be criticised as well as lauded for their public acts, praise when given is of no value, and medical editors had better abandon their vocation.

The editorial complained of was, under the circumstances, not very severe. The facts set forth, with one exception, seem to be established by the evidence contained in the last issue of the *Record*; and, finally, the editor of that journal offered the use of its columns to Dr. Hammond, and has done everything he could, consistently with proper self-respect, to deal fairly with the subject. What Dr. Hammond has to gain by an appeal to court it is very hard to perceive. He certainly cannot believe public professional opinion will be influenced by the decision of the jury; and, if there be any justice, no money damages will ever in this case "salve the wound that honor feels." It is but a step from the sublime to the ridiculous, and certainly the verge of the height seems to be crumbling under Dr. Hammond's feet.

ACCORDING to the London *Lancet*, Sir Cordy Burrows, one of the directors of the Brighton Aquarium, entertained at luncheon Mr. George Somes, Mr. Henry Lee, F.L.S., and Lieutenant-Colonel Chichester, when the *pièce de résistance* was boiled octopus. It was pronounced to be very palatable, resembling boiled lobster and skate.

The cuttle-fish is used as food in various parts of the world, notably in China. It is too rare upon our coast to be of any economic value. Probably other sea-monsters might be of value. We have by way of experiment eaten, in small quantity, the transparent jelly of the ordinary jelly-fish as raw oysters are eaten, and found it not unpalatable.

CORRESPONDENCE.

PHILADELPHIA, September 21, 1874.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—I have been for some months past making a new use of chloral hydrate,—viz., that of a preservative for hypodermic injection solutions, and so far have been satisfied with its reliability and safety.

Having experienced both the inconveniences of dissolving morphine or other alkaloid powders extemporaneously, and the vexing delays which will occur at night in waiting for the compounding of prescriptions, I feel that the annexed suggestion will assist those who wish to possess a *reliable* means at the *needed* moment, securing certainty and saving time.

My formula is—take of hydrate of chloral, two grains; diluted acetic acid, two drops; distilled water, four drachms (fluid).

In this menstruum any *alkaloid* usually employed (or any other of the *materia medica* which may be liable to decomposition) may be dissolved or suspended in the proportion customary with each practitioner.

I have experimented with the alkaloids morphia, atropia, and strychnia, also bromide of potassium, and in varying proportions. The solutions have kept free from *visible* alteration for several weeks, and their effect after this time was as certain as when recently compounded. A slight musk-like odor is developed in a few days, but the clearness of the solution is in no wise impaired.

Respectfully,
W. MACPHERSON, M.D.

RESECTION OF THE LOWER JAW, LEAVING RIM OF SUPPORT.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

THROUGH the kindness of the editor of the *Dental Cosmos* I send you cuts which exhibit a case operated on by myself some five months back, in which the cure became perfect without any necrosis of a very delicate rim left, and under a constitutional condition which renders a notice of it valuable to a class of practitioners who have occasion, like myself, to be informed of precedents in such direction.

The patient, a Miss C., 17 years of age, of exceedingly delicate organization and of *decidedly strumous* tendency, required operation on account of a cysto-sar-coid tumor, which extended from the first molar tooth of the left side to the first bicuspid of the right, and which involved the body of the jaw to a depth extending midway between the dental canal and the base of the bone. Exposing the parts, as shown by the cut, with the ex-

pectation of a necessity for the full section of the bone, it was determined (seeing that the tumor might be removed and yet a rim left) to risk a return of the disease and the probability of necrosis, together with the possibility for a second operation, rather than produce, without an assured absolute necessity, the hideous deformity consequent on the complete section.

The precedent of interest in the case lies in the fact that here is another instance in which the inferior dental vessels have been removed, and a long span of bone survives, and this under most adverse

constitutional condition. The patient is now perfectly

well, and is without greater deformity than is seen in any person who has lost the lower teeth. The chin, of course, and the articulation of the remaining teeth have their normal relations preserved, while even the lost parts are capable of being perfectly represented in an artificial denture which I shall shortly prepare for her.

J. E. GARRETSON, M.D.

ALEXANDRIA, VIRGINIA, September 22, 1874.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

IN an interesting letter from Dr. R. J. Levis, dated Norwich, England, giving a condensed report of the proceedings of the British Medical Association, the remarks of Dr. Marion Sims are given relative to the question of chloroform-narcosis and resuscitation therefrom. In this statement the opinions of Drs. Campbell, of Paris, Schuppert, and Holmes, of the United States, are quoted in favor of the view that this state is really due to anæmia of the brain.

As this is a question which claimed much of my thought and attention some years since, with a view of furnishing additional evidence in favor of that belief, I deem it not inappropriate here to refer to a most interesting case published by myself in 1860, bearing on this very subject, and, so far as I am aware, the only one on record which proves by actual ocular demonstration the truth of this opinion almost beyond a doubt. This was a case of extensive fracture of the cranium, in which a large portion of the os frontis, measuring at least three by one and a half inches, was driven into the anterior lobes of the brain by the kick of a powerful horse. The bone was crushed into ten or fifteen pieces, and imbedded into the substance of the brain, portions of which were forced out. It was a frightful opening in the skull. The patient, a boy, was perfectly conscious, and so rebellious that it became necessary to resort to chloroform to induce quiet during the tedious operation of removing the bones. Perfect consciousness and mental intelligence were remarkable features in the case. Indeed, the patient stated that from the moment of receiving the injury the memory was unbroken and complete of every circumstance. This case was attended by myself, then residing in the town of Yanceyville, North Carolina, and published in the October number of the *American Journal of the Medical Sciences*, 1860.

During the protracted operation, the patient was placed under the influence of chloroform three or four different times. As the anterior lobes of the brain were fully exposed to view and were terribly lacerated, every opportunity was offered to witness the conduct of the organ under the action of the anæsthetic, and again while free from it. These demonstrations were of an exceedingly interesting character, and, in my own opinion, establish absolutely the fact that cerebral anæmia is the inevitable result of the action of chloroform, and that death, apart from organic disease of the heart, is due alone to this condition of the brain.

The following quotation from the article alluded to is given for the purpose of showing the action of chloroform on the physical operations of the brain. I am not aware that any similar occasion has ever been offered wherein the phenomena of anæsthetic action on the physical changes in the brain were so completely exposed to investigation.

"Our preconceived ideas in regard to the specific action of anæsthetics would very naturally deter us from their use in this kind of case. Their effects in this instance on the brain, at least so far as the circulation is concerned, were perfectly manifest. Here a large portion of the surface of that organ was exposed to view, and any physical change in the brain produced by the agency of the anæsthetic could be easily observed. Considering the various speculations in regard to this influence, the effects in this case were highly interesting. Hemorrhage, which had been free previously, ceased almost entirely after the full anæsthetic impression had been made. It is conceived by the profession that under the impression of chloroform the actual vascularity of the brain is increased; that absolute congestion takes place. The present case afforded an ample opportunity to determine this question definitively. Whenever the anæsthetic influence began to subside, the surface of the brain presented a florid and injected appearance. The hemorrhage increased, and the force of the cerebral pulsations became much greater. At these times, so great was the heaving and bulging of the brain that we were compelled to suspend operations until they were quieted by a repetition of the anæsthetic. Then the pulsations would diminish, the cerebral surface recede within the opening of the skull as if by collapse, the organ becoming pale and shrunken with a cessation of the bleeding. In fact, we were convinced that diminished vascularity of the brain was an invariable result of the action of chloroform.

"The changes above referred to recurred sufficiently often during the progress of the operation, in connection with the anæsthetic administration, to satisfy us that there could be no mistake as to cause and effect.

"Again, these changes began invariably to appear with the earliest influence of the agent. As consciousness diminished, in a corresponding ratio there was diminution of vascularity of the brain; and as the mental powers would return, the contrary would occur."

The subject of this injury, though having sustained the loss of a considerable portion of the anterior lobes of the brain, was still living after the war; his intellect never having been impaired for a moment from the reception of the injury.

Respectfully,

BEDFORD BROWN, M.D.

SULPHATE OF ZINC IN RHUS-POISONING.—Dr. Charles H. Humphreys, of Ohio (*Am. Med. Journal*), extols a strong solution of sulphate of zinc as a curative of rhus-poisoning: a half-ounce or more to a pint of water, applied every hour, by means of a sponge.

SELECTIONS.

THE PLAGUE IN MESOPOTAMIA AND NORTHERN AFRICA.

THE reappearance of plague in Mesopotamia and Northern Africa is a fact of peculiar interest, even if regarded solely from the historical associations of the malady. The locality of reappearance in Mesopotamia is contiguous to the scene of the outbreak of 1867; the locality of reappearance in Northern Africa was the scene of the outbreak of 1858. Plague is believed to have disappeared from Egypt in 1844, and it is not known to have existed in Northern Africa from that date to 1858. In the last-named year the disease broke out in the regency of Tripoli, at Bengazi, the ancient Berenice, and spread over that portion of the district of Barca which was known among the ancients as Cyrenaica. Mesopotamia had been free from plague upwards of thirty years (no certain case had been known since 1834) when, in 1867, the disease appeared, and spread to some extent among the Arab tribes inhabiting the marshy district which lies west of the Euphrates, between the ruins of Babylon and the great shrine of Shiite pilgrimage, Nedjef (Meshed Ali).

The present appearance of plague in Tripoli began at Merjeh some time during the first quarter of the year. Merjeh is situated to the southeast of Bengazi, about twenty hours distant, on the plain of the same name. It is a new town, built on the site of the ancient Barca. When the place was visited by Hamilton in 1856, a fortress, begun a year before, and "several small houses in progress, destined to form the nucleus of a town," alone existed. Now the number of houses is said to be sixty-four, including certain excavations in the rocks, beneath the fortress, used as dwellings, and the general state of squalor seems to rival that of Bengazi, known among the Turks, from its persistent plague of flies, as the "fly kingdom." Thirty cases of plague, twenty-seven of which were fatal, have been verified by a medical commissioner, Dr. Laval, as occurring between the 7th and 21st of June, among a population of about three hundred. On the last-named date, Dr. Laval, unhappily, was himself struck down with the disease, and he died on the 27th.

In 1858 the plague which then prevailed in the district extended to Merjeh. The plain, or, as some term it, the valley, of Merjeh, is an extensive tract of "mingled pasture and cultivation," hemmed in by richly-wooded hills. Although from its extent designated a plain, and from its being surrounded by hills, a valley, yet, say the Beecheys, in their narrative of exploration on the north coast of Africa in 1828, this plain and valley, from its being situated "in the top of a chain of mountains of no inconsiderable elevation, must also be considered as a tract of table-land raised far above the level of the sea." The plain is a favorite resort of the Bedouin tribes in the summer months, from the numerous pools and lakes formed there by the water coming from the neighboring hills. The different travellers who have visited the plain describe it and the district which surrounds it as of great beauty; and those geographers who hold that the gardens of the Hesperides were in the Cyrenaica appear to have much to justify their belief in certain physical characters of the district.

The outbreak of 1858 occurred in the midst of famine, caused by a continuance of drought in several successive years, and the consequent diminution and ultimate destruction of crops and exhaustion of supplies. Famine is not stated to have preceded or accompanied the existing outbreak of plague in Merjeh.

The scene of the present diffusion of plague in Meso-

potamia is on the Lower Euphrates, south of Musseyib. The disease first showed itself at the close of February or the beginning of March last among the Affij Arabs, who occupy the northern portion of the great marshes on the east bank of the river. The infection quickly spread to the neighboring tribes, and, attacking both banks of the river, it extended along the stream from Devanieh upwards to Hillah. On the west bank of the stream the infection spread also to Nedjef (Meshed Ali) and Kerbella (Meshed Hussein) to the edge of the desert,—in fact, traversing the district which was the scene of the outbreak of 1867.

Since the commencement of June, plague does not appear to have extended beyond the area described, and there is reason to hope that it is now dying out within it. No clear knowledge exists of the loss of life occasioned by this diffusion, and it is hardly likely that such knowledge will be obtained. The medical commission appointed by the Ottoman government to investigate the diffusion has been able to satisfy itself of the nature of the disease, but has been foiled in its attempts to ascertain the extent of prevalence among certain tribes and in certain localities.

The recurrence of plague among the tribes inhabiting the marshes of the Lower Euphrates, as the recurrence of the malady in the district of Barca, is highly suggestive of inquiry regarding the development of the disease, if it were possible to carry out such an inquiry among the isolated and savage tribes affected. The Affij Arabs, among whom plague first appeared this year on the east bank of the Euphrates, seem to have like habits and like surroundings as the Beni-Taraf Arabs, among whom the disease first appeared on the west bank of the river in the outbreak of 1867. Both tribes live in the marshes, and for a third of the year amid the annual inundation of the Euphrates; both occupy reed huts covered with matting, and both cultivate and live largely on rice. Mr. Kennett Loftus, who visited the Affij Arabs twice, once in 1849 and again in 1854, describes their "fragile towns" as consisting entirely—

"Of reed huts, the reeds being tied in large bundles and nearly arched overhead. This primitive construction is covered externally with thick matting, impervious to rain. The riches of the Affij are indicated by rows of huge reed cylindrical baskets, containing the grain upon which they subsist. Rice is produced in great abundance along the edges of the marsh; but the whole of their fields were at the time of our visit and for a third of the year entirely under water. Communication is kept up, as on the marshes of Hindieh, by means of long, sharp, pointed terradas, constructed of teak, and measuring twelve or fourteen feet long by a yard in width." (*Chaldæa and Susiana*, p. 91.)

The same writer's description of the Hindieh marshes, on the west bank of the Euphrates (the scene of the outbreak of plague in 1867), as seen from Birs Nimrûd, deserves quotation:

"The view from the summit of the Birs Nimrûd is very extensive, and its utter desolation has been the theme of frequent observation. No one can stand there and survey the scene around without being struck with the literal fulfilment of Isaiah's prophecy,—'I will make it a possession for the bittern, and pools of water; I will sweep it with the besom of destruction, saith the Lord of Hosts.' Spreading out like a vast sea upon the north and west is a marsh, which all the labors of the ancient and modern rulers of the country have never been able to subdue. In certain seasons the waters of the Euphrates rise above their ordinary level and flood the whole surface of the lowlands of Chaldæa, confirming every word of the prophet. Bordering upon this marsh, a few spots attract the eye and relieve the long level of the horizon. Due south stands the little tomb

of the prophet Ezekiel, and at the distance of fifty miles, in the mirage of early morning, may be discerned the mosque of the sainted Ali, glistening like a speck of gold as the beams of the rising sun play upon its surface. Nearer at hand, on the northwest, are the twin domes of Kerbella, the burial-place of Ali's slaughtered sons. The edge and islands of the marsh are at times dotted with encampments of Khuzeyl Arabs, and with the telescope may be distinguished the numerous flocks of sheep and camels, while the hum of busy voices can be distinctly heard a distance of full six miles across the waters." (Page 33.)

About the same time that the outbreak of plague occurred among the Affij Arabs, and the disease appeared in Northern Africa, it was also rumored that plague had shown itself at Revanduz, in Turkish Kurdistan, and in the vicinity of Bana, in Persian Kurdistan. Both places are on the confines of the district which was the scene of the outbreak of 1870. At the close of that year, after an interval of forty years, plague broke out among the villages situated between the rivers Jagatu and Tatawa, southeast of Lake Urumiah. It appeared first in those situated in the swamps, and of which the inhabitants were employed in the cultivation of rice. During the winter the infected villages were cut off from the surrounding country by the snow, and when communication was reopened with them they were found to have been wellnigh depopulated by the disease. As the spring advanced and the roads became free, the inhabitants took to the hills and migrated into neighboring districts, carrying with them the infection, which now quickly spread over a considerable extent of the mountainous region. The inhabitants of this part of Kurdistan escaped the horrors of the famine which prevailed in Persia in 1871, but it is not so certain, as some believe, that the communities first attacked by the plague did not suffer much privation. The outbreak had been preceded by murrain among the cattle and by defective and diseased crops; and it is probable that the populations of the infected villages suffered great straits during the winter of 1870-71.

Famine during the past winter (1873-74) was widely present in Asia Minor, but neither the district of Kurdistan from which the rumor of plague now comes, nor the district which is the scene of the present outbreak on the Lower Euphrates, appears to have suffered, and no report of plague has come from the famine-stricken districts.

It might seem from the recent recurring outbreaks of plague as if the disease were about once more to become a prominent epidemic. The possibility of a reappearance of the disease in an epidemic form has not been overlooked by the different writers on the subject; the subsidence and even apparent extinction of the malady in countries where it was once endemic not being regarded as affording any surety against its recurrence, so long as the sanitary condition of the inhabitants remains unchanged. The limitation of the recent outbreaks to communities removed from ordinary observation, and among whom the first beginnings of the disease could not be traced, suggests that plague, although now more rarely observed in a diffusive form, may not so entirely have disappeared from its former seats of prevalence in the Levant as is commonly believed, and that these recent outbreaks may possibly be recrudescences rather than reappearances. Whichever be the truth, the practical lesson is the same; and Europe, while not regarding these outbreaks with indifference, ought to contemplate them without anxiety. In the present state of medical and sanitary knowledge and practice, plague among European nations should excite no greater emotion, as it does not call for other measures of precaution or treatment, than typhus. In the Turkish dominions in Asia and Africa the case is, however, different. There

racess and populations, as in the present infected districts, have to be dealt with, among whom the sanitary regulations of a civilized community are impossible. But the sanitary organization of the Turkish Empire seeks to close the different routes by which the infection of plague may travel from an infected locality, and it is now attempting to bring the various centres of Mohammedan pilgrimage in its dominions under systematic medical and sanitary supervision, so as to prevent them becoming as heretofore great *foci* of epidemic diffusion.

As we write, a report has reached this country of the appearance in Western Arabia of a disease resembling plague, and the Egyptian government has put in operation the most stringent measures for isolating the affected districts, and for placing under supervision and subjecting to quarantine arrivals from the Hedjaz in Egyptian ports. It has also decided, according to official report, to cut off all communication with the regency of Tripoli by land and by sea. The locality in which the disease suspected to be plague has shown itself in Western Arabia is Dogar (or Doga), a town built of brushwood and reeds, and lying at the foot of the hills, a day's journey northeast of the fort of Gonfudah. Here the encampment of an Arab tribe has been attacked. If the suspicion that this disease be plague should be confirmed, it is to be feared that the disease will also be found to exist in other parts of Arabia, as a consequence of dissemination from the Lower Euphrates and from Meshed Ali and Kerbella.—*London Medical Record*, Aug. 26, 1874; from the *London Times*, Aug. 17.

GLEANINGS FROM OUR EXCHANGES.

PECULIAR EFFECT OF NITRITE OF AMYL (*The Practitioner*, September, 1874).—Dr. J. Crichton Browne, while administering nitrite of amyl to a girl who was in the *status epilepticus*, noticed that yawning was produced, and that whenever the inhalation was interrupted the yawning ceased; whenever it was resumed the yawning recommenced. One or two other similar observations, made by himself and his colleagues, induced him to make a series of experiments by administering nitrite of amyl to persons during sleep. Out of fifty-seven cases in which he had avoided waking the patient, in forty-two there were distinct movements of the mouth, consentaneous with flushing of the face. The most common movements were a depression and elevation of the lower jaw, as if in the act of chewing, and a smacking of the lips. Ether was found, as a rule, to merely deepen sleep without producing any movements whatever; ammonia always awoke the patient. It appears, therefore, that nitrite of amyl, when inhaled during a state of unconsciousness, has a specific action upon the motor centres of the mouth, and calls into action, by preference, the muscles of the lips and lower jaw. Whether it performs this action reflexly or through the agency of the vaso-motor apparatus is as yet undecided.

REST IN THE TREATMENT OF PHTHISIS (*The Practitioner*, August, 1874).—Dr. Frederick T. Roberts believes the following to be the only ways in which any mode of rest can be expected to be serviceable in the treatment of phthisis.

1. By keeping the lungs at rest, more or less generally or locally, disease may be prevented, its spread checked, and its cure promoted where it has already developed.

2. Possibly, by diminishing the flow of blood through the lungs, active mischief may be to some extent checked.

3. By looking to the condition of the air inhaled, any irritation from this source may be prevented.

4. Local symptoms may be considerably relieved, and untoward accident, such as rupture of a vessel, averted.

5. General destruction of tissue may be prevented by making but little call on the patient's efforts; and this is a matter of considerable importance in some cases.

POISONING WITH BURNETT'S FLUID (*The British Medical Journal*, September 5, 1874).—Dr. H. M. Tuckwell reports the case of a female, æt. 21, who took about four ounces of Burnett's fluid (solution of chloride of zinc) with suicidal intent. This was followed by burning epigastric pain and tenderness, retching, and vomiting, and inflammation of the soft palate, uvula, tonsils, and pharynx. The lips, mouth, and tongue were unhurt. Life was prolonged for one hundred and sixteen days, during which time the vomiting continued; she had tetanic spasms in the right fore-arm and hand, and grew more and more emaciated until death. The bowels were moved only three times. As the termination approached, she became covered with innumerable petechiæ and vibices, giving the body a bluish mottled appearance. For fifty-seven days life was supported by injections; water only being taken by the mouth.

There were remarkable fatty changes in certain organs of the body and in the muscular tissue, co-existing with the extreme general emaciation of the body. These changes were of two kinds. In the liver, kidneys, and pancreas there was a positive infiltration or accumulation of fat, not a substitution or degeneration; for, after the fat had been removed from them in the process of mounting microscopical preparations, the natural structures were found to be perfect; the epithelial lining of the tubules of the kidney more especially was as regular and well preserved as in the illustrations given in books. In the muscles, on the other hand, there was a true fatty substitution or degeneration.

A HANDY METHOD OF EXAMINING MORBID TISSUES MICROSCOPICALLY (*The British Medical Journal*, September 5, 1874).—Take a portion of nerve-tissue, about the size of a large pin's head, from a thoroughly defined locality, press it out gently under a covering-glass on a slide, remove the covering-glass, and apply to the mass left on the slide a drop of "Judson's simple (aniline) magenta dye," diluted with eight drops of water; with a needle, mix the dye and the nerve-matter carefully, and cover the preparation with a clean covering-glass, again gently pressing it out to such an extent that light can pass through it. On submitting a specimen thus prepared to the microscope, it will be found that the cells, the nuclei of the neuroglia, and the blood-vessels, are beautifully tinted a deep crimson color, leaving the other tissues almost unaffected. Morbid products are also well brought into view, either by their ready absorption of the dye, as in the case of amyloid bodies, or by their refusal to take on the tint, as in the case of colloid bodies. Hæmatoidin accepts the color all too readily, but the practised eye soon recognizes its appearance. Pigmentary degeneration of cells is well shown, nucleus and nucleolus being thoroughly demonstrated; the poles can also be traced for long distances.

PERCHLORIDE OF IRON IN POST-PARTUM HEMORRHAGE (*The British Medical Journal*, September 5, 1874).—Mr. W. P. Swain records two cases of post-partum hemorrhage, in the first of which all the usual resources, except galvanism, had been tried in vain, and in the second so rapid and large was the loss of blood that nothing short of *immediate* arrest could have saved the patient. The injection of perchloride of iron was entirely successful in both instances.

INFLAMMATION OF THE WRIST-JOINT (*Medical Record*, September 1, 1874).—In a case of fracture of the forearm, with phlegmonous erysipelas and inflammation of the wrist-joint, it was deemed possible to save the limb if the joint could be placed perfectly at rest and at the same time all pressure could be removed from the articular surfaces. To fulfil these indications, Dr. Sayre used an apparatus which he describes as follows. Take a piece of sole-leather, long enough to reach from the digital extremity of the palm of the hand to near the flexure of the elbow, and wide enough to half or two-thirds surround the arm. Dip it in cold water, and make it thoroughly flexible. Cover it with a piece of adhesive plaster, plaster-side out, long enough to go completely around it lengthwise, and lock. Now, having covered each opening with a piece of oakum, apply the leather-lined plaster to the palm of the hand, mould it, and secure it with a roller bandage as far as the wrist. Having arrived at that point, grasp the hand already covered, while an assistant grasps the arm near the elbow; then, making extension and counter-extension until the patient tells you that all pain is relieved, bring the remainder of the leather-lined plaster against the fore-arm, and secure it with a continuation of the bandage. In this way all pressure is removed from the articular surfaces, pain is relieved, and an apparatus is afforded which retains everything at perfect rest.

AXILLARY ANEURISM—LIGATION OF SUBCLAVIAN ARTERY—RECOVERY (*Canada Medical and Surgical Journal*, August, 1874).—Dr. George Ross reports the case of a young man who suffered from a right axillary aneurism of two months' duration at the time when he came under observation. His right arm hung cold and livid by his side, all motion in it being limited to slight action of the biceps and deltoid muscles. The second and third phalanges were rigidly flexed upon those of the first row; there was not the faintest pulsation in either the radial, the ulnar, or the brachial artery. In the axilla there was a tumor the size of a large lemon, which fluctuated, pulsated forcibly, gave a very perceptible thrill to the hand, and by auscultation a whizzing bruit. The pulsation was entirely controlled by pressure on the subclavian over the first rib. Digital impression was faithfully tried for forty-eight hours, but was unsuccessful and was abandoned. It was then decided to ligate the subclavian in its third portion; and this was done. The ligature was of carbolized catgut, the end being allowed to hang out of the wound. He subsequently had diarrhœa and some troublesome febrile symptoms, but at the end of four weeks the wound had entirely closed in its deeper part, and the mass of the aneurism had shrunk to about one-fourth its original bulk. About this time he had a severe cough, and expectorated a large quantity of thick, dark pus, but afterwards made a very good recovery.

MONOBROMIDE OF CAMPHOR (*The Practitioner*, August, 1874).—Dr. Bonneville believes that from about forty experiments, which lead him to attribute powerful sedative properties to monobromide of camphor, he is justified in drawing the following deductions:

1. Monobromide of camphor diminishes the number of beatings of the heart, and determines contraction of the blood-vessels of the iris and eyelids.

2. It diminishes the number of inspirations.

3. It lowers temperature in a regular and constant manner. In fatal cases the lowering increases till the end. In those which recover, the lowering is followed by an elevation of temperature, which returns to its initial figure, but in a longer time than that during which the lowering was effected.

4. Monobromide of camphor possesses undeniable

hypnotic properties. It seems to act principally on the cerebral nervous system.

5. It does not seem that the medicament is got accustomed to, and its protracted use determines rather rapid loss of flesh in cats and guinea-pigs. He has used it with advantage in delirium tremens, insomnia, infantile convulsions, paralysis agitans, chorea, hysterio-epilepsy, etc.

COMPARISON BETWEEN THE ACTION OF BROMAL HYDRATE AND THAT OF CHLORAL HYDRATE (*Edinburgh Medical Journal*, July, 1874).—1. Bromal hydrate is a more active substance, physiologically, than chloral hydrate. Four or five grains will cause death in a rabbit which would require about twenty grains of chloral.

2. Chloral hydrate produces, in small doses, or soon after a large dose, marked hyperæsthesia, followed by anæsthesia. Bromal hydrate never produces hyperæsthesia, and anæsthesia only when the animal is in such a state of coma that there is no hope of its recovery.

3. Chloral hydrate does not usually produce great contraction of the pupil. Bromal hydrate always does.

4. Chloral hydrate acts chiefly on the cerebral hemispheres, and never causes convulsions. Bromal hydrate acts less vigorously on the hemispheres, and more on the ganglia at the base of the brain and on the spinal cord,—the animal frequently dying in a state of opisthotonos.

5. After death from chloral hydrate, fluid is rarely found in the short sacs of the body. In the case of bromal, fluid is almost invariably found.

6. Chloral hydrate does not usually stimulate the salivary glands to the same extent as bromal hydrate does, but in this instance there are exceptional cases in which chloral causes excessive secretion of saliva in animals.

AMENORRHOEA (*The Medical Record*, September 1, 1874).—Prof. Alexander Skene considers anæmia as the most common cause of amenorrhœa. After having successfully treated this condition by the ordinary remedies,—iron, quinia, alcohol, etc.,—there are still some cases where the amenorrhœa persists after all the constitutional troubles have disappeared. It then becomes necessary to use means with a view to excite directly the uterus to action. Most so-called emmenagogues act by producing irritation and congestion of the pelvic organs, and are always uncertain, and often injurious. In their place for several years Prof. Skene has given chloride of ammonium in five-grain doses every three or four hours, and has obtained good results. He believes that it acts by favoring the rapid exfoliation of the epithelial lining of the uterine mucous membrane. Perseverance is an important element in the management of such cases. There are few exceptions to the rule that, no matter how long-continued the amenorrhœa may be, the menses will ultimately be normally established.

PARALYSIS FROM FRIGHT (W. Jelly, in *Brit. Med. Journal*, 1874, No. 695).—The patient in this case was a Spanish woman, aged 22, who had previously been in good health, but who, immediately after a cannon had been discharged in her immediate neighborhood, found that she was unable to advance a step.

Her lower limbs were stiff, and soon the left, and, later, the right one became very weak, while her gait was waddling and unsteady. Her general health was good, the functions of defecation and urination not interfered with, and her menstruation was not interrupted.

There was no disturbance of sensation, but there was moderate pain in the spinal column from the eighth dorsal to the third lumbar vertebra, and the lower extremities felt cool. Numerous forms of treatment were tried, but without result. Jelly thinks that owing to the

sudden change of the pressure of the air in their immediate neighborhood the meninges of the spinal column were torn.

THE HYPODERMIC USE OF QUININE (*New York Medical Journal*, September, 1874).—Dr. Stephen Rogers considers the use of quinine hypodermically a dangerous experimental medication, and rarely justifiable. He believes that the whole subject may be epitomized as follows:

1. The hypodermic method of giving quinine involves a surgical operation of considerable discomfort, not to say pain, and hence should not be employed unless under circumstances rendering it indispensable.

2. The operation is extremely liable to be followed by more or less severe and protracted local inflammation, abscess, and very possibly tetanus. It should therefore be avoided if possible.

3. It is very easy to avoid these pains, discomforts, and dangers, without in the slightest degree lessening the chances of recovery of the victim of miasmatic disease.

4. The risk connected with the hypodermic method is not at all necessary, for the available means to accomplish the results which that method claims are abundant, and in no respect less reliable or more expensive.

THE DISPERSION OF TUMORS BY PUNCTURE (*The Lancet*, August 22, 1874).—Deputy Inspector-General Cameron calls attention to the fact that in Eastern countries the natives have from time immemorial been accustomed to attempt to bring about the absorption of the enlargements of the liver and spleen, so common in hot, malarious countries, by the use of puncture with long, sharp stiletts of considerable thickness. He never in any instance saw inflammatory or other bad symptoms produced by such operations. Other enlargements may be made to disappear by the same method. Chronic glandular swellings have been greatly benefited in this way, and it is even possible that such growths as fibrous tumors of the uterus might be dispersed by it. In the case of an infant a few months old, who had a tumor about the size of a pigeon's egg, smooth, movable, painless, and situated in front of the upper edge of the quadratus lumborum muscle halfway from the spine, a firm, deep puncture produced a speedy disappearance of the growth.

FIBROUS ANCHYLOSIS (*Medical Record*, September 1, 1874).—Dr. Louis A. Sayre believes that in those cases of fibrous anchylosis which most closely assimilate bony anchylosis, a distinguishing feature is that if movements are made at the joint, and any motion whatever is secured during the manipulation necessary to a thorough examination of the case, it will be followed by more or less of pain within twenty-four hours. For when bony anchylosis is present, no movements at the joint can be made, consequently pain will not be produced at the point of anchylosis. This rule will be found to be reliable. The subsequent occurrence of pain in and about the joint, even if there be no apparent motion, will justify measures calculated to give to it gradual restoration of motion.

TREATMENT OF HÆMORRHOIDS.—Dr. William Colles (*Dublin Jour. Med. Sci.*, June, 1874), having under his care a severe case of "bleeding piles" where all former treatment, including applications of fuming nitric acid, had been of no avail, concluded to try injections of perchloride of iron. For this purpose twenty minims of the ordinary tincture were injected into each mass by means of a hypodermic syringe. The injection caused less pain than the nitric acid, and one administration sufficed to remove the hæmorrhoids completely.

EXCISION OF THE SHOULDER-JOINT (*The British Medical Journal*, September 5, 1874).—Sir John Rose Cormack reports the case of a man from whom he removed the head of the humerus, with three and a half inches of the shaft, which had been shattered by a rifle-ball. He entirely recovered, without any loss of sensation, and having all the motions of the arm except those of elevation and abduction, the deltoid being the only muscle much affected.

HYPODERMIC INJECTION OF ERGOTIN IN PURPURA HÆMORRHAGICA (*The British Medical Journal*, September 5, 1874).—In a case of purpura hæmorrhagica, occurring during the progress of typhoid fever, and immediately after a severe epistaxis, two injections of one grain each of the liquid extract of ergot completely arrested the hemorrhage from the nose, stomach, and bowels, and the patient, who was previously at the point of death from syncope, rallied and made a perfect recovery.

LOCAL ACTION OF IPECACUANHA (*The Practitioner*, September, 1874).—Dr. De Mussey records a case of purulent ophthalmia in a new-born infant, in which, after all other remedies had failed, he succeeded in producing a cure by the use of the following decoction:

R Ipecac root, ʒss;
Water, ʒv.

Boil for ten minutes, and, when cool, strain off.

IODIDE OF POTASSIUM IN ACUTE AND CHRONIC BRONCHITIS AND ASTHMA (*The British Medical Journal*, September 5, 1874).—Mr. W. H. Spurgiss has used iodide of potassium in over one hundred cases of the above diseases, and with invariable success, now rarely giving anything else.

MISCELLANY.

BLOOD-DRINKERS.—Upon inquiry at slaughter-houses, it is found that there are nearly two hundred persons in the city of New York who are in the habit of drinking blood flowing warmly from oxen, for strengthening purposes and for the cure of certain diseases. A lady is reported to have spoken to an inquirer as follows: "Professor Velpeau, of Paris, prescribed blood for me. I was consumptive and hastening to the grave. It has prolonged my life fifteen years. I had the utmost repugnance for it at first, but now a half-pint of hot blood from a well-conditioned ox is the greatest luxury of my life. My sister's baby so far has been preserved and nourished with little else but blood. I know twenty persons who drink it in my own neighborhood to whom I have recommended it. It has extraordinary effects on some people, especially women, but should not be resorted to unless there is absolute weakness of the system." On a visit of the inquirer to a slaughter-house in Tenth Avenue, near Forty-second Street, he found a delicate-looking woman with a sickly boy holding a glass to the blood which ran from an ox with his throat cut. Both drank two or three glasses in turn, and departed with an appearance of added vigor. One of the butchers was asked whether he ever drank blood, and is stated to have replied to the following effect: "Sure an' I do, now; why not, now? Faith,

an' ye couldn't tell the difference between it an' milk. It's just as swate, shure, and in the winter it's warm and foine. Bedad but it's stringthenin', sure. Hould on, an' I'll get ye a drap. It's best warrum—runnin' right from the baste." The proprietor said, "All last winter we had men, women, and children every morning to drink blood. They always imbibe beast's blood; never the blood of sheep. Some of them wince a bit at first, but, when you close your eyes, blood warm from the beast's neck has just the same taste as warm milk from the cow. We don't charge for the blood, excepting when we sell it to sugar-refiners." The blood of bees is asserted to be more efficacious for weak lungs than cod-liver oil.—*The Laboratory*.

The statistics of the New York Board of Pharmacy indicate the wide area from which the American drug trade is recruited. During the year ending June last they registered 62 proprietors and 101 assistants. Of the proprietors there were—natives of the United States, 24; Germany, 19; England, 4; Ireland, 9; Canada, 3; and Austria, Russia, and Cuba, 1 each. Of the assistants, 37 were born in the United States, 32 in Germany, 8 in England, 5 in Ireland, 3 in Canada, 4 in France, 3 in Russia and Poland, 2 each in Scotland, Austria, and Sweden, and 1 each in Norway, Cuba, and Costa Rica.

DR. FRANCIS E. ANSTIE, so widely and favorably known to the profession throughout the world for his masterly treatise on neuralgia and his other numerous contributions to medical science, died on Saturday, September 12, after an illness of only three days. His attack is said to have been produced by exposure to sewer-emanation while examining the sanitary defects of a school at Wandsworth. In him the British profession loses one of its brightest ornaments.

"NOTHING NEW UNDER THE SUN."—Doctor Mordtmann, of Constantinople, publishes in the *Gazette Médicale de l'Orient* some curious details he has discovered in some old Oriental chronicles, tending to show that the Siamese Twins, as well as the Sisters Milly and Christine, had prototypes in former times. According to these Byzantine chronicles, there came from Armenia to Constantinople, in the year 744, a monster, consisting of two children born of one mother. These children were attached to each other at the epigastrium, so that they faced each other, the other parts of their bodies being regularly formed. During their sojourn in the Byzantine capital numbers flocked to see this monstrosity; but, as the twins were superstitiously regarded by the ecclesiastical authorities as being of bad augury, they were expelled the city, to return again when a comparatively enlightened emperor ascended the throne of the Cæsars. One of these twins died, and the most skilful physicians endeavored to divide the survivor from the corpse at the point of juncture, in the hope of saving his life. The operation, however, only served to prolong its duration for three days.—*London Medical Record*.

THE INSTINCT OF BIRDS.—The foresight of birds of a coming epidemic of cholera has been occupying the attention of the *Jardin Zoologique*. That journal states that, a few days previous to the terrible ravages of cholera in Galicia in 1872, all the sparrows suddenly quitted the town of Przemyśl, and not a single bird returned until the end of November, when the disease had entirely disappeared. The same circumstance was remarked in Munich and in Nuremberg. During the attacks of cholera at St. Petersburg and Riga in 1848, in Western Prussia in 1849, and in Hanover in 1850, every swallow and sparrow forsook the town, and remained absent until the eradication of the scourge.—*British Medical Journal*.

THE FAMILY BONAPARTE.—Madame Letitia Rattazzi, one of the members of the family Bonaparte, has for some months been visiting the principal towns of Europe, to study the ways and means of establishing a hospital which shall be especially devoted to the treatment of cancer. As is well known, several of the members of this family have succumbed to this terrible disease. The first deposit will be 150,000 francs, to which will be added a biennial prize of 5000 francs for the best work on the subject, as well as a sum of 20,000 francs for him who shall describe the true cure for cancer.—*London Medical Record*.

A "PHARMACIEN" of Paris has been condemned to pay a fine of five hundred francs for selling pastilles of calomel without a physician's prescription.

DR. SOUBEIRAN, assistant professor at the Paris School of Pharmacy, has lately been appointed to the professorship of pharmacy in the Montpellier school.

NOTES AND QUERIES.

MEDICAL EDUCATION.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—For the past ten years I have associated with all classes of physicians, not only in the United States, but also in different European countries; and, after a careful investigation, I find nothing so pernicious in the advance of medical science as the admittance into its ranks of gentlemen whose preliminary education has been neglected, and who are unqualified to discharge the duties which they have assumed. Most of the European colleges require that the students spend twelve years in their preliminary medical education, and, after they have passed their collegiate examination, they are required to pass the State "Faculty Board" before they are allowed to practise; and then it is certified whether they are physicians, surgeons, or both. I knew quite an eminent physician, from London, who was required to appear before the "State Board" in South America previous to practising, and failed to pass his first examination, and also his second, six months afterwards, and had to return to London, although he was a regular graduate of medicine. Had he come to the United States, the question would never have been asked if he was a graduate or not. It is a well-known fact that in no place in the civilized world are medical diplomas given out so promiscuously and unceremoniously as in the United States.

Only three medical colleges in the United States are recognized by the South American State Faculty, and even the graduates of those colleges are required to have a certificate from the State Board before they are allowed to practise; while in Europe no one is allowed to practise unless he first passes the State Board. For some time during the late European war I had as assistants two medical cadets who had served five years at the University of Berlin, and who were well qualified to be

ranked as physicians, but the laws of the country would not allow it. Myself and forty-two other American graduates who had passed the appointed board of the German Empire were assigned on probation duty for six weeks in Coblenz, under the surveillance of the State Faculty, to test our qualifications before we were assigned to special duty. So much for Germany. In our free and enlightened country the medical refuse from the four quarters of the earth are allowed to practise and hold responsible positions with all the dignity of the learned profession. In Biblical writings and in ancient history we find the priests the men of medicine, as they were the most learned; and it was not until the twelfth century that the Council of Tours sent forth the famous edict forbidding the clergy to practise the healing art. In European countries the physicians are required to be better educated than the general class of society,—equal to that of the priests; while in this country we have in the profession the most ignorant, unrefined, and uneducated. In this, as well as in all other cities in the Union, we have a large number of so-called doctors who have never attended a single lecture or received any preliminary education; but still they are recognized as physicians, and admitted into medical associations as dictators to those who are properly educated. It is impossible for any man to discharge the duties of a physician if he is not qualified for it. His every action has a tendency to bring into disrepute the profession in general. It is impossible to elevate the character of the medical profession to its proper standard until there is some legislation in the matter prohibiting colleges from granting diplomas as they now do, and preventing quacks of every variety from practising medicine. During the past six months I have endeavored to impress upon the minds of certain members of Congress the importance of passing a national law forcing a reform in the medical profession. I think every true physician and the people from one end of the land to the other should rise, pointing to the graves of the friends and relatives who have been victims of the ignorant and of quacks, and demand of Congress a national law elevating the standard of medical education and requirements. Until this is done, the physicians as a class will have neither character, standing, nor dignity as they should, nor will the people be free from impostors.

A. TREGO SHERTZER, M.D.

BALTIMORE.

FOUR AT A BIRTH.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—On the evening of September 18, a negro woman, aged over 40, in this vicinity, gave birth to four well-developed children, three girls and one boy. One of the girls was still-born, but I am confident that pressure during a protracted labor produced its death. There were two placentas; three of the children were attached to one, while the dead one was attached alone to the other. No physician was present during her labor, an old negress being the only attendant, and her description of the accouchement was highly interesting and graphic in the extreme.

Respectfully,

JOHN W. PITTS.

BERLIN, MD., September 22, 1874.

At a special meeting of the Medical Board of Charity Hospital, held September 22, 1874, the following resolutions were adopted:

"Whereas, It has pleased the All-wise Providence to remove from our midst our friend and colleague Dr. Washington Atlee Hoffman, be it therefore

"Resolved, That the Medical Board of Charity Hospital express their heart-felt sorrow at his death.

"Resolved, That we hereby tender to the family our sympathy in their bereavement.

"Resolved, That a copy of these resolutions be presented to the medical journals for publication; and that the Medical Staff of the hospital attend the funeral in a body.

"H. LEAMAN,
"Secretary."

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM SEPTEMBER 22 TO SEPTEMBER 28, 1874, INCLUSIVE.

SMITH, JOS. R., SURGEON.—When relieved by Assistant-Surgeon Koerper, to proceed to Fort Monroe, Virginia. S. O. 190, Military Division of the Atlantic, September 24, 1874.

KOERPER, E. A., ASSISTANT-SURGEON.—In addition to his duties at Detroit, Michigan, to relieve Surgeon Smith of his duties at Fort Wayne, Michigan. S. O. 190, c. s., Military Division of the Atlantic.

SATURDAY, OCTOBER 10, 1874.

ORIGINAL COMMUNICATIONS.

REPORT OF CLINICAL CASES OF DISEASES OF THE EAR, THE CHIEF SYMPTOMS OF WHICH WERE "TINNITUS AURIUM," OR NOISES IN THE EARS.

ILLUSTRATIVE OF A PAPER PUBLISHED IN THE "PHILADELPHIA MEDICAL TIMES," JUNE 27, 1874.

BY LAURENCE TURNBULL, M.D.,

Physician to the Department of Diseases of Eye and Ear, Howard Hospital, Philadelphia.

(Concluded from page 5.)

WE have now and then very favorable results from the galvanic excitement in isolated cases, as may be noticed by a reference to the author's statement of cases of nervous deafness treated by Brenner's formula;* yet Brenner states that he had failed in seventeen cases of tinnitus. In a carefully prepared paper by H. Schwarze, of Halle,† he observes, "I am far from denying favorable effects of the galvanic excitement in isolated cases, but I have not been able to convince myself at any time of any real and permanent results from galvanization. . . . Moreover, we must remember that a series of (more recent) ear-troubles, also of such whose causes must be sought for in the cranial cavity, are capable of a spontaneous cure. Whoever has not frequently convinced himself of this fact, is apt to over-estimate his therapeutics. The physician who is in the habit of treating all diseases by the preference of one remedy, as, for example, electro-therapeutics, of necessity over-estimates the results of his favorite remedy."

Case VI.—Extreme deafness, with noises, from sun-stroke.

Henry C. K., aged 44, has suffered from complete deafness of eight years' duration; supposed cause, sun-stroke. He had applied cold water to his head after exposure to the intense heat of the sun; no pain; says he has ordinary noises in the ear. His deafness commenced in California. Has also granular pharyngitis, extending into Eustachian tubes, with ulceration of the mucous membrane lining the vomer. Left Eustachian tube closed. The right Eustachian tube is pervious, but much narrowed. Cicatrix on left membrana tympani. Right membrana tympani more normal in appearance. Watch not heard on either side. Tuning-fork heard only on temporal bones. The patient having tried all manner of treatment without success, the writer perforated the membrana tympani, and, with Weber's improved tenotome, divided the tendon of the tensor tympani, with the assistance of the resident physician of Howard Hospital, Dr. Parish. The operation was followed by pain and a few drops of blood.

Directed oil of turpentine, ten drops every three hours, in mucilage of gum arabic, until all the acute symptoms had disappeared; electricity was then applied by Dr. Warrington, who has furnished the following notes of the case:

July 21.—First application of electricity. Stöhrer's battery, six cells. Cathode in ear; anode in right hand. No impression.

July 22.—Eight cells. Slight sensation of sound.

August 1.—Eight cells. Continued to apply electricity six times a week, about the same force and the same effect; hearing constantly improving. The throat treated by scarification and application of tincture of iodine and glycerin, equal parts. Improvement. Internal treatment, iodide of potassium from four to eight grains three times a day, combined with tincture of columbo or ginger. Also chlorate of potash, ʒij; tincture of chloride of iron, fʒij; syrup, fʒj; glycerin, fʒj; water, fʒij.—M. Tablespoonful doses three times a day. The patient felt so much better that he desired the operation of tenotomy of tensor tympani of the other ear.

September 20.—On performing the operation, he was immediately deprived of the power to hear words in that ear. Inflammation and suppuration followed. Eustachian tube became very patulous. On speaking into the ear, words were seldom distinguished, but the sound was intense and distressing. Throat more inflamed. Injected the ear with sulphate of zinc, gr. iii; sulphate of morphia, gr. i; water, ʒi. Symptoms of improvement, and some return of hearing. In three weeks applied electricity, eight cells, slight effect.

October 10.—Throat improved; hearing in right ear good, also in left ear.

December 11.—Hearing for sounds better than at any time since the operation. Throat well; able to hear words in conversation better than ever before.

Case VII.—Concussion, with extravasation of blood into labyrinth, terminating in an acute attack with deposit in the mastoid cells, with deafness and severe tinnitus of left ear. (Reported by Dr. Parish, late resident physician of Howard Hospital.)

Edward McH., native of Wales, aged 45. He stated that, when passing up the Mississippi River during the war, on the flag-ship "Hartford," under Commodore Farragut, a cannon was fired immediately over his head, the left ear being towards the gun. So close was he that his hair was burned. He immediately became insensible, and, on arousing in about an hour, found himself very giddy, and with pain in his head, but not in the ears. Nausea and vomiting were present, and occasionally occurred during the following two or three days. Prior to this accident he could always hear well, and never had any trouble with either ear. Since the accident, the left ear has been almost completely deaf, but at no time has he had tinnitus in the left ear. At the same time hearing diminished in right ear, but was not abolished.

About September 15, 1873, right ear lost almost entire appreciation of sound, when tinnitus and buzzing supervened.

About October 1 a purulent discharge appeared in right ear.

October 27.—At present both membranes perforated; left apparently drawn in; purulent discharge from right meatus. Had both washed out, and applied argenti nitras in solution.

October 30, 1873.—Hearing improved in right ear; left ear still very deaf; perforation of right apparently healing; that of left still very large. Solution of argenti nitras passed into left ear; it is felt in the pharynx, and is tasted by the patient.

November 2, 1873.—Hearing much improved in right ear, but severe pain in it and mastoid cells and over right side of head, with swelling. Dr. Turnbull punctured mastoid cells with a bistoury down to the bone, giving severe pain at the time, and causing the man to become quite pale and faint.

November 6.—Returns entirely free from pain. Hearing much improved, and tinnitus entirely gone. Patient much pleased with result.

* Turnbull, Clinical Manual of the Diseases of the Ear, p. 389.

† Archiv für Ohrenheilkunde, March, 1874.

Case VIII.—Concussion, with symptoms of extravasation of blood into labyrinth or semicircular canals.

During the summer of 1864 Dr. Parish saw a soldier in apparent general good health, very deaf, and with constant and great tremulousness of head and upper extremities chiefly, but also to some extent of lower extremities; very giddy on attempting to walk, and gait very unsteady. He stated that a few days previously, while lying in front of the breast-works, a heavy cannon was fired in close proximity to him, and that the ball passed but a few feet from his head. He was instantly rendered unconscious, and continued so for a few hours. On returning to consciousness, found himself in condition as above. He was on his way home on furlough when Dr. Parish saw him, and he was not again heard from.

Case IX.—Congestive tinnitus, the result of working at a heated furnace with head bent to one side; all the ordinary remedies employed, with tenotomy of the tensor tympani; no improvement.

Margaret A., aged 36, an intelligent woman, living as a domestic, applied at Howard Hospital with intense tinnitus. She has had charge of a large furnace; while looking into and raking it when in full blast she was suddenly seized with headache, giddiness, and noises on the side nearest the heated part, in the winter of 1871. She consulted Dr. H., a young and intelligent physician, a resident of one of our large hospitals, who syringed her ear, giving her quinia, etc., but with no relief. She then visited the Philadelphia Eye and Ear Infirmary, and was under the judicious care of the aural surgeon of that institution for some time, but his treatment was of no benefit to her. Came to Howard Hospital in January, 1873. A careful examination was made, and the Eustachian tubes were found open in both ears. Right ear, the one in which the noises disturbed her, the membrana tympani was retracted, with axillary rotation of the handle of malleus; no catarrhal trouble in pharynx. After employing all the local remedies, as the air-douche, injection by the double catheter, and washing out Eustachian tubes, also injecting into the middle ear solution of potash and hydrate of chloral, with no benefit, she was advised to have perforation of the posterior fold. She willingly consented, and returned on April 10. The writer then perforated the posterior fold of the membrana tympani in the presence of Dr. Mathews, resident physician in Howard Hospital (1871), and passed a warm solution of bicarbonate of soda, by a closely-fitting air-tight syringe; this gave her considerable pain, and she was ordered a solution of zinc sulphas, gr. iii to the ounce of warm water, to be applied at night, also a quarter of a grain of morphia if in pain, with extract of hyoscyamus applied around the ear. The perforation kept open for one month, but with no relief to the noises.

On May 5, 1873, I performed tenotomy of the tensor tympani, and applied electricity to the pharyngeal orifice of the Eustachian tube, in the presence of Dr. Parish, with Weber's tenotomy; the patient did not complain of much pain; I directed a mixture of spiritus terebinthinæ, etc., as advised by Weber-Liel.

On the 12th of May I injected the middle ear with solution of zinc sulphas, gr. vi to ʒi aquæ, which gave her pain; directed hydrate of chloral to relieve her.

She returned to the hospital on the 15th, 18th, 21st, and 29th,—no improvement. On the 29th she desired to have the operation repeated, in hopes of some benefit; this was again done. She suffered but little during the last operation; no bleeding as at the first operation. She could pass air by the perforation, but there was no improvement in the noises.

Called at the hospital, by request, in six months. December, 1873, still troubled with the noises; no impair-

ment of hearing since the operation. No pain. Membrana tympani shows two spots of opacity. Able to attend to her duties; is as well as before the operation.

Case X.—Complete deafness, with no tinnitus; not any loud sounds heard, and no articulate sounds recognized even by the use of the most powerful ear-trumpet.

A. H., aged 55, a lawyer by profession, and a gentleman of fine literary taste and philosophic knowledge, applied to the writer during the winter of 1873. The history of his case was as follows. He gradually lost his health, and with it his hearing, about one year before he applied; he still heard sounds when he placed himself under the care of a physician of this city, who, he stated, first introduced steam into his middle ear, and then blew cold air, which was followed by total deafness (doubtful). When he came to the writer he was under Prof. Agnew's care for his general health, and the writer made but a casual examination, and advised him to continue, and found both Eustachian tubes open,—one more than the other,—with dense opacity of both membrana tympani, without tinnitus, showing complete paralysis of the auditory nerve. In partial paralysis we have subjective or pseudo-subjective sensations. This patient again presented himself in the fall of 1874, and was very desirous of having something done for his hearing. His health was improved, but with the improvement no sounds were heard. We had therefore to inform him that no means that we knew of would be of any benefit to his hearing. His only brain-symptom was vertigo.

Case XI.—Deafness, but hearing by the use of the ear-trumpet; tinnitus with distressing vertigo; patient relieved by the operation of tenotomy of the tensor tympani.

The following are the notes of this case: George B., aged 45, Princeton, Indiana, applied May 16, 1874. Has been a merchant in the neighborhood of Pike's Peak; was a soldier for one year, but was discharged on account of his deafness and his liability to fall from dizziness. History: has had no children's diseases, but had intermittent fever for ten years, with enlargement of the spleen. Has never had any pain in his ears, but on one occasion accidentally struck his left ear with much force, and had a discharge of yellowish pus for one week. In the year 1859 heard as well as any one; became interested in a mill, when, owing to exposure, his hearing began to leave him. He became a soldier, but he could not hear the fife or drum; and yet he could distinguish some of the low notes of the piano but none of the upper notes; could hear the human voice in his own ear-trumpet, made by himself, of thin platinum in the form of an auricle, which was so light in weight that he balanced it in one ear. The treatment he had been under consisted in syringing the ear, and soon after it was followed by a pulsating noise in the left ear, which was at first intermittent, but after a time became constant. He had in his right ear sounds like a letting-off of steam. He had been under physicians at his home and in New York City. Examination: external meatus normal; chronic inflammation of membrana tympani of left ear, with injections along the handle of the malleus, with deposit of lymph and adhesions. This was evidently the effect of the blow. Right membrana tympani injected, with depression, with deposit of lymph on the vessels along the handle of the malleus. Rhinoscopic examination of the orifices of the Eustachian tubes: left, open and patulous, with enlarged glands; right not so much open. Tuning-fork heard best in the right ear; left not so perfect, showing conduction of the bones of the head, and not entire paralysis of the auditory nerve, as in the other case. Examination by exhausting the air by Siegle's pneumatic apparatus repeatedly applied, afforded no relief to the pulsating noises.

Pressure by shutting the nose modified them somewhat. Faradization with the sponge on wire insulated produced a sound like that of a fly on a window-pane; on increasing the power the pain became much more intense under the ear and in his teeth, but no relief to the tinnitus. By the use of the author's double otoscope, heard the sound of the air in the right Eustachian tube loudest.

May 26, decided to operate by tenotomy of the tensor tympani, and to break up the adhesions as the only chance for relief. This was performed at Howard Hospital, assisted by the resident physician, Dr. J. Barr (1874), and in the presence of two medical students. On perforating the drum, there was some difficulty in dividing the tendon of the muscle, which was unusually thick and resistant, and the patient experienced considerable pain, owing to the adhesions which had to be broken up by passing the knife under them. To prevent inflammation, the ear was carefully covered up, and a mixture of terebinthinæ spiritus and ammonii chloridi given three times a day.

Reported same day: parts looking very well and open; all pain ceased by 7 P.M. the evening of the operation. Feels relieved of a certain disagreeable sensation in his head (vertigo),—feeling of falling.

May 30.—Still continues well; injected a solution of one grain of sulphate of zinc through the opening; not much pain; this was repeated twice.

The patient left for his home in a few days after the operation, and when he arrived the writer received the following letter from him, in which he states, "I arrived at home all right; no trouble with ear. The left Eustachian tube is now more open than it ever was; hearing about the same in both ears; had no trouble with my head since the operation."

I gave him certain instructions to be carried out, also advised a more extended trial of the faradic current, as Brenner's formula had been obtained by its use in our first experiment with his deaf ear. This, it is true, is rather like a confirmation of Schwarze's second conclusion, "that Brenner's normal formula is obtained in absolute deafness;" but there must be no tinnitus, for we have no such result in cases where there is absolute paralysis of the auditory nerve (see case before referred to).

The following are the conclusions of the eleven cases reported: four were cured, two much improved, two improved, one not improved, and two not treated. One of those not improved is a form of deafness accompanied with distressing noises, where the patient apparently was in sound health a few hours before; this is followed by apoplectic symptoms, with giddiness, and is due to hemorrhage into the labyrinth, and is known as Ménière's disease. The same results shown in another from injury may occur from fracture through the bony labyrinth by contre-coup. In one we had absolute paralysis of the acoustic nerve, with little or no tinnitus.

"Nolet,* of Leyden, has made experiments concerning the origin of pulsating tubular noises which have been so much discussed, the main results of which are here given, because they are important. Vascular or pulsating noises are produced in tubes of equal calibre, if the velocity of the current be great; and this velocity must be the greater the smaller the diameter of the tubes and the smoother their walls. The rougher their walls are, the sooner

will noises be produced. If there be a strictured place in the tube, a noise becomes perceptible already at a rate of velocity when there would be no noise perceptible if the narrowing were not present. When the velocity of the current was considerable, a quivering was to be felt before and behind the strictured place, which was more readily produced in tubes with thin walls than in such as had thick walls. When the tubes were partially widened, noises were produced in them by a greater velocity of the current (? translator). The noises are produced by the viscidness (vertices of the fluid), and not by vibrations of the walls of the tubes nor by rhythmical friction (?) of the out-flowing jet."

The treatment of such pulsating noises is of two kinds: first, constitutional treatment if the disease depends upon thinness of the blood or a want of certain elements; these must be supplied, if from want of iron, by chalybeates, if from want of fibrin, by wheat, etc.; if the other important elements are wanting, blood in some form itself, as the expressed juice of beef, like Valentine's, or by lamb's blood taken warm. If the blood is too thick or viscid, it must be reduced by salines. If the noises are very distressing, resort may be had to nervines and agents that will control the violent action of the heart, as aconite, digitalis, with chloral hydrate or fluid extract of valerian, *Prunus virginiana*, or water of the bitter almond or orange-flower. Mechanical means are also to be tried, by compressing the jugular vein over the highest point of the hyoid bone. The observations of Benedict, Türk, and Politzer confirm us in the opinion that pressure over the mastoid apophyses would, in some instances, modify these subjective noises. By removal of the narrowed condition of the meatus auditorius, as performed by Larrey and Cloquet, or by some mechanical and surgical means as related in the author's work, p. xvi. In a certain class of cases of chronic catarrh of the middle ear, Politzer has recommended the closing of the external meatus by wax or cotton charged with wax. Schwartz employed for the same purpose a ball of gutta-percha oiled, softened by means of warm water, or, as the writer prefers, gas-heat and olive oil. Luca has employed and recommended the rarefaction of the air by fitting the external meatus with an instrument like Siegle's pneumatic apparatus, especially in catarrh of the cavity of the tympanum. The condensation of the air in the auditory canal by the same instrument gives, sometimes, good results in the cases of pressure of the stapes, or stirrup, over the fenestra ovalis, or oval window.

Then follows puncturing of the membrana tympani, recommended as early as 1722, and first received into favor as a legitimate operation in surgery about the year 1800, for deafness and sounds in the ear. We have repeatedly performed this operation, and in certain cases with success; again, we have operated with no relief to the noises. Schwartz, who has performed this operation over one hundred times, has established it in cases where there has been an accumulation of mucus, blood, or pus. He prefers a transverse incision in the posterior and inferior part of the membrana tympani.

* Trollich, *Ohrenheilkunde*, Fifth (German) Edition, p. 507. Nolet of Leyden (see *Archiv für Heilkunde*, 1871, xii.).

Dr. Luca* has also resorted to this operation in the treatment of deafness and noises, by a division of the posterior fold or pocket for the purpose of reducing the tension of the membrane of the drum. Where he has had the peculiar rattling sound denoting a collection of secretion, which is also to be perceived by a sufficient transparency of the membrane, after cutting the posterior fold he extends the cut to about the middle of the membrane, in order to facilitate the escape of the not unfrequently very viscid and tenacious secretion. He has performed this operation (division of the posterior fold) up to 1870 forty-eight times in forty-five cases, as follows: First, in cases without demonstrable adhesions, fourteen operations: greatly improved, seven; a little improved, seven; not at all improved, none. Second, in expressed otitis media adhesive, twenty-seven operations: greatly improved, five; a slight improvement, eleven; not at all improved, eleven. Third, in genuine catarrh of the cavity of the drum, at the same time letting out the secretion, seven operations: of these, six were greatly improved, one a slight improvement. Politzer performs the same operation by incision of the posterior fold (not pocket) of the membrana tympani. His incision is a longitudinal one, at right angles to the long axis of the fold between the short process of the malleus and the peripheric end of the fold.† Of the operation of tenotomy we have already given our experience in the cases above reported.

A CASE OF PLACENTA PRÆVIA, WITH REMARKS.

BY W. H. PARISH, M.D.

MRS. O'D., a native of Ireland, æt. 30 years, of fair general health, had passed through two ordinary labors, and had reached the termination of the eighth month of the third pregnancy, when, to escape the attack of a drunken husband, she leaped from a window about five feet down to the pavement. A few minutes subsequently, while lying in bed, a profuse uterine hemorrhage came on, lasting until a number of cloths were saturated and until the woman became pale and weak. She, however, sent for no physician at that time, and in a few days was again at work. About two weeks afterwards another flooding came on at night, while in bed, and without assignable cause. I was sent for, and found her with all the evidences of having sustained an excessive loss of blood. This was also attested by the condition of the bedding, etc. A digital examination showed the os to be about the size of the finger, and the placenta could be distinctly felt completely closing the internal orifice. The bleeding had stopped, and there were no evidences of incipient labor. I gave some morphia, and enjoined the recumbent posture, with a cooling regimen. After watching her for a few hours I left, but returned frequently during the subsequent days. About ten days later a sudden and profuse hemorrhage came on. I reached her in a short time, and found that the bleeding had again been excessive, but had then ceased. The os was the size of the two fingers. The placenta was easily felt, and no free membrane was in reach. Slight labor-pains were present.

Having to be absent for a short time, I obtained the assistance of one of our students, Mr. Percival Loder, and instructed him on the first appearance of bleeding to introduce a tampon of soft old rags, and to saturate with a solution of equal parts of water and Monsel's solution that portion which would be against the os uteri. Hemorrhage soon returned, and Mr. Loder successfully tamponed the vagina, and, at my request, began then the administration of ergot. I returned in two hours, accompanied by Dr. C. A. Robinson, of Alabama, then on a visit to this city. We found the tampon had proved effectual. It was removed. We found the os fairly dilated, and evidently dilatable. The placenta we found to be then occupying about four-fifths only of the dilated os; the other one-fifth occupied by membranes only, and lying to the mother's right. On removal of the tampon, bleeding returned. I ruptured the membranes; the liquor amnii escaped freely, but the uterus did not respond, and the hemorrhage continued. I attempted the forceps. Dr. Robinson made faithful endeavors to steady the "movable head" by external pressure. Introducing my right hand so as with the dorsum of my fingers to press the placenta gently to the mother's left, I slipped the first blade of Wallace's forceps along the palmar surface of my hand past the placenta, and to the side of the child's head,—the position being the first one. The other blade was introduced without difficulty to the opposite side of the head, and the two were locked. My finger found, however, that the head had not been grasped. Quickly removing the second blade, I adjusted the first blade, without withdrawing it, to the side of the head, and, reapplying the other blade, locked them. My finger again showed, however, that the head had a second time escaped. It had probably moved its position, and the resiliency of the placenta had possibly pressed the first blade also from its position. I withdrew the forceps, introduced my left hand, and, seizing one leg, made version and delivered by the feet, somewhat promptly, as the cord was very feebly pulsating. The placenta became detached, and showed at the vulva as the shoulders were emerging. There had been no prolapse of the cord, and its attachment was at its usual site,—the centre of the placenta.

The uterus was followed down by external compression; clots were removed from the uterus with the hand; ice applied internally and externally, the cold douche, compression of the abdominal aorta, were all ineffectual. The hemorrhage continued. The woman's condition was becoming a critical one. With pale and pinched features, colorless lips, and a scarcely perceptible pulse, she was restless, tossed her arms about, said that there were noises in her ears, and that things were dark to her. A little more blood lost, and death would have resulted. Now, however, wrapping a piece of cloth around my finger and saturating it with Monsel's solution, I introduced it into the uterus, and swabbed the area of placental attachment. The uterus contracted, the bleeding ceased, and the woman's life was saved. The child, too, was living, though feeble, and of a livid pallor. It died at the end of four hours.

Under the use of stimulants, with a nutritious diet, and the employment of quin. sulph., gr. xii, and morph. sulph., gr. ss daily, the woman slowly improved. On the fourteenth day she ventured to steal out of bed, and had a severe rigor, followed by intense fever, with induration and pain in the left iliac region. On the twenty-first day, another rigor. The temperature ran up to 105° Fahr., but gradually fell under the quinia and morphia, with the employment of the tinct. digitalis and the tinct. ferri chlor. During the fifth week she was allowed to sit up, and from that time rapidly improved, so that on May 1 the recovery was complete. The delivery occurred on the 15th of February, 1874.

* Dublin Journ. Med. Sci., Oct. 1871, p. 322.

† Monatsschrift für Ohrenheilkunde, Jahrgang ii. p. 51.

The etiology of placenta prævia is undetermined, though it has been noticed that in multiparous women with leucorrhœa—*i.e.*, in those in whom there is increased width of uterine cavity and increased smoothness of uterine mucous surface—the complication is most frequent (Schroeder). Mrs. O'D. had been suffering with leucorrhœa, and was of course a multipara. Leishman tells us also that the trouble is apt to recur.

The leap from the window preceding the hemorrhage, and the subsequent discovery of the placenta in its abnormal position, would have served as a strong fact to have fixed in the minds of those obstetricians who lived prior to the time of Portal (1785) the belief that its unusual position was due simply to the detachment of the placenta from its ordinary site at the fundus, and its gravitation to the more dependent position over the uterine orifice.

The diagnosis is always, perhaps, sufficiently easy. It will be noticed that what was here at first complete became of its own accord, as the os dilated, partial placenta prævia.

The frequency of this trouble, according to Boivin, is 1 in 2554; Clark, 1 in 2596; Collins, 1 in 1492.*

The prognosis of this, "one of the most dangerous accidents incident to a parturient woman," depends in individual cases pre-eminently upon the treatment, whether prompt and judicious. And in the statistics of different series of cases, the proportional mortality, of the mothers at least, seems to vary somewhat widely with the plan of treatment instituted.

From rupture of the membranes, the tampon, and turning,—the preferred treatment with the mass of obstetrical authorities,—the maternal mortality has been given by Simpson at 27.48 per cent.; by Trask, 27 per cent.; by Lee, 33 per cent. So that in placenta prævia, under the ordinary treatment, about one-third of the mothers die.

Schroeder, in his late authoritative work, recommended that for the hemorrhage coming on prior to labor absolute rest in the dorsal position should be enjoined, and that if bleeding persists, the tampon must be resorted to, remembering, however, that this remedy may superinduce labor. "The treatment during labor," he says, "is very simple. 1, a tampon to the vagina until the cervix is so dilated that the foot can pass through it; 2, one foot is brought down by the combined manipulation, and gradually the foot is more strongly drawn upon." If the attempt at version does not succeed, he does not, with the view of increasing uterine contractions and causing the head to be pressed against the bleeding orifices and thus to aid in checking the hemorrhage, rupture the membranes immediately; "for," he says, "the uterus is not always thus aroused; and if the os is not dilated or sufficiently dilatable to admit of delivery, it would become necessary to resort to the tampon, and under such conditions there would be considerable risk of a concealed hemorrhage. So that version failing

when the os is the size of the two fingers, he continues with the tampon without rupturing the membranes, until the head is being pressed sufficiently firmly against the os to stop the hemorrhage, or the os is sufficiently dilated to admit the passage of the hand and the turning of the child. If the foot has been drawn through a narrow os the leg will serve as a tampon, and, as the os gradually dilates, the child should be gradually drawn through. If, however, the os admits of rapid delivery, and the child is living, but *very feeble*, he permits the resort to rapid delivery, but not to the extent of too much endangering the life of the mother. On page 312 he says, "When the os is sufficiently dilated so that the head can enter it, it may be extracted, if necessary, by means of the forceps. The *accouchement forcé*," he says, "always avoid." Schroeder does not give the results of treatment in his hands. Such, however, with slight modification, is the teaching in the main of most authorities, and the great majority of practitioners would give it as the line of their practice.

Some twenty years ago, Simpson, noticing with others that hemorrhage almost always ceased when the placenta was delivered spontaneously before the birth of the child, and that the woman almost always recovered, advocated, in cases of hemorrhage, the artificial detachment and delivery of the placenta, letting the child remain until the ordinary process of labor should deliver it. He collected accounts of one hundred and forty cases, including both those of artificial extraction and natural expulsion, in which there were only ten deaths, or a maternal mortality of 7.14 per cent., certainly presenting, though the statistics are somewhat faulty, a much diminished risk to the mother. His views, however, chiefly because of the almost certain death of the child, and because the bleeding did not stop as certainly after artificial as after spontaneous delivery of the placenta, were subsequently modified so that he advocated the treatment only in exceptional cases. Cazeaux says that only "in case of death or non-viability of the child should the placenta be extracted." Such is also the teaching of Schroeder, and perhaps of all authorities of to-day.

Simpson thought that the bleeding came from the detached portion of the placenta, and his object in separating the placenta entirely was to prevent the blood getting into it and then getting out of it. No one entertains this view now, for it has been well established that the hemorrhage comes from patulous vascular orifices in the uterus itself; and whether the placenta is separated in part or throughout its entire extent, bleeding will occur unless these orifices are closed; and this is accomplished almost solely through the contraction of the muscular tissue of the uterus. The placenta must become separated sufficiently to admit of dilatation of the os, and it is not detached beyond this until the engagement of the head. For a number of years Dr. Barnes has advocated the separation, by means of the finger, of the placenta from what he calls the "orificial zone,"—*i.e.*, from an area of the uterus equal to the area of the os when dilated to the extent necessary to permit the passage of the

* Hodge, p. 479.

child. He claims that by this means the os is allowed to dilate more rapidly, that the contractions are more complete, and that thus the uterine orifices are more effectually closed and the hemorrhage obviated. He says that unless the hand is passed into the uterus there is no danger of detaching the entire placenta; for the finger can sweep over a surface of a diameter of only six inches, whereas the surface of placental attachment has a diameter of nine or ten inches. Moreover, the diameter of an os through which a child can pass is just about six inches.

For hemorrhage coming on before labor, he considers rupture of the membranes the "most generally efficacious remedy." If bleeding continues, he introduces a tampon, preferring laminaria tents, passed into the os. He removes the tampon every hour, in order the better to watch the progress of the case, for occult hemorrhage might occur. Usually the labor will thus go on satisfactorily; but the bleeding may continue, the os may not dilate, and there may be no active labor. Now he dissects the placenta from the "official zone," and "often the hemorrhage ceases" and the os retracts. At the same time he encourages uterine contractions by means of the binder, of ergot, and of stimulants. If the uterus contracts, labor will go on safely. If the uterus is inactive, he introduces one of his dilators, so that between the binder and the bag the bleeding is held in check. If hemorrhage should still continue, or if the position of the child is other than that of the head, one of the feet must be brought down by the bipolar method as soon as the os permits it. It is not unusual for the position of the child to be an abnormal one.

Of sixty-nine cases thus treated in his hands, the maternal mortality was one in eleven and a half; certainly much better than one in three or four.

This treatment is recommended by Tanner and by Leishman, but is not referred to by Schroeder, nor in the older works of Cazeaux, Ramsbotham, Hodge, etc. The physiological considerations upon which it is based, with the favorable results obtained by Dr. Barnes, render the remedy well worthy of our adoption in suitable cases.

Under whatever treatment, the infant mortality is between sixty and seventy per cent. The child dies usually of asphyxia, the mother usually of loss of blood, either from its immediate or its remote effects.

We have not referred to any difference in the treatment of partial and of complete placenta prævia, and perhaps a distinct difference could not well be drawn, although from rupture of the membranes in the partial form we are most apt to obtain satisfactory results.

In the case we have reported, the want of success in the ready application of the forceps illustrates the advantages of version, unless the head is held firmly in the pelvic canal by uterine contractions.

The failure of all the ordinary methods in use for checking post-partum hemorrhage, the persistency of the hemorrhage, and the threatened death of the woman, with the speedy, gratifying effect of the ferruginous styptic, would seem to show unmistakably that the woman's life was saved by the local use

of the iron,—a remedy highly advocated, especially by Dr. Barnes; strenuously opposed, especially by Dr. Snow-Beck.

The manner in which we used it is recommended by Leishman in the post-partum hemorrhage from placenta prævia, and would be indicated whether the bleeding was due to paralysis of the cervical segment or to a tearing of the tissue of the cervix.

TREATMENT OF VENEREAL BUBOES.

BY H. E. WOODBURY, M.D.

IN the *Medical Times* of September 19 I find under this heading a translation of Sauszinski's method of treatment. A brief statement of the plan I have pursued since 1864 may prove of interest to the profession.

In that year I was connected with Armory Square General Hospital, Washington, D.C. A soldier came to me with a large bubo, and informed me that some of the medical officers had been for weeks treating it, but that it was larger, harder, and more painful than before. I directed him to apply hot flaxseed-meal poultices, changing them frequently. This he did faithfully, and on the evening of the second day I operated as follows:

A sharp-pointed bistoury was passed through the tumor longitudinally; that is to say, the knife was entered at a point of the gland nearest to the ilium, and carried entirely through it in the direction of the pubis. When the knife was withdrawn, from the two small openings issued a little blood mixed with pus. With a small rubber syringe, I then injected a drachm or two of tincture of iodine, diluted (one part to four of water). This, being forced into one of the openings, flowed out freely from the other. Rest for a few days was enjoined, and the only dressing used was lint, saturated with a weak solution of potass. permanganat., a roller being applied as a compress over the lint, and as much pressure being made by means of a bandage as the patient could comfortably bear. There was but little suppuration, and no sloughing. In a short time it was evident that adhesion of the integument to the deeper tissues had taken place, and a cure was soon effected. Iodide of potassium was given (in ten-grain doses) during the treatment. The only traces of the bubo that remained were a slight induration of the part, and two small cicatrices at the points of entrance and exit of the knife.

The unsightly scar that follows the old method of treatment,—free incision,—and the slow process of repair attendant thereon, render the method herein proposed more acceptable to the patient and more satisfactory to the surgeon. I never make free incisions in these cases.

In some cases that have occurred in my practice I have succeeded in avoiding the use of the knife, as follows:

The patient is confined to his bed; a half-brick, covered with flannel,—a single thickness,—is laid upon the bubo. A lump of ice is kept upon the brick, and as it melts the flannel is saturated with ice-water. I have seen a large bubo disappear in

twenty-four hours under this treatment by cold and pressure; a combination of iodine and iodide of potassium in syr. sarsap. being administered internally. If this course be resorted to at the proper time, we believe that the necessity for surgical interference would often be avoided. Of one fact we are fully convinced by experience,—if the knife be used, the smaller the incision, the better and more rapid the cure.

WASHINGTON, D.C., September 23, 1874.

CHOREA IN THE NEGRO.

BY CHARLES G. POLK, M.D.,

Philadelphia.

IN reply to the query of Dr. S. Weir Mitchell, I will state that in the spring of 1860 I treated a mulatto in South Milford, Delaware, suffering from chorea. The man was a ship-carpenter by trade, large, strong, and otherwise healthy, and about 30 years of age. In the pure negro I have never seen a single case, although during our civil war I had, temporarily, six colored regiments under my charge; and, in addition to my duties as post-surgeon at Gainesville, Florida, 1865, I performed the duties of Freedman's Bureau Surgeon, and had for six months a large field of observation. The rarity of the disease had attracted my attention, and I tried to find a case in Charleston, South Carolina, without success. In 1867, while post-surgeon at Greensboro', North Carolina, I did nearly all the work of the unfortunate bureau surgeon; saw much of negro practice, and did not witness a case even in one of the mixed race. I am consequently led to believe that if it ever happens in the negro, the occurrence is extremely rare.

TRANSLATIONS.

TRANSFUSION OF LAMB'S BLOOD.—Drs. Fiedler and Birch-Hirschfeld, in Dresden (*Deutsches Archiv für Klinische Medizin*) have been investigating the question of the utility of lamb's blood for transfusion, and have performed the operation in a series of six cases in the hospital, where their progress could be carefully observed and registered by experienced observers. In addition to these, of which full details are given, the operation was performed eight times in Dresden by other physicians. The conclusions drawn from these cases are far from being as favorable as those reported by Gesellius* and Hasse,† who have lately revived the much-vexed question of a century ago, concerning the adaptability of the blood of animals for transfusion.

The six cases reported were suffering from chronic (tubercular) pneumonia, in different stages of the disease. When the operation was performed, the blood was led, from a tube connected with the carotid artery of a yearling lamb (which had half an hour previously received two grammes of chloral hydrate, hypodermically), into a vein in the patient's fore-arm. Soon after the commencement of transfusion the patient generally experienced a sense of warmth and fulness in the

face, followed by severe abdominal and lumbar pains, nausea, dyspnoea, with an increasing sense of oppression, jactation, hyperæmia, with injection of the conjunctiva, passing into symptoms of collapse; the pulse, which at first was strengthened, gradually became thread-like, the extremities cold, and the face cyanotic. The transfusion was generally continued until the complaints of the patient and his general appearance forbade further interference, which was at the expiration of from eighty to two hundred and thirty-six seconds, in the cases reported, and after fifty to one hundred and fifty grammes of blood had been transfused.

In each case there was a marked elevation of the temperature, which attained its maximum (39° to 41.2° C.) in from one and a half to five hours after the operation, and was not proportional with the amount of blood transfused. In from sixteen to twenty-four hours the temperature fell to the usual range it occupied before the operation, before resuming which, however, in some of the cases, there was a more or less rapid temperature-collapse, the thermometer showing a difference between the maximum and minimum temperature of from 3° to 5.8° C.

In all of the cases the operation was shortly followed by a severe chill and a profuse sweating. Icterus appeared, in one case, the day succeeding the transfusion, which was attributed to staining by hæmatin liberated by solution of the old or new blood-corpuscles. In one case there was an eruption of herpes labialis on the second day, and in three urticaria appeared on the fifth to the seventh day, lasting from forty-four to forty-eight hours. This was thought to be due to an irritation of the vaso-motor nerves; to which was also attributed the paralysis of the small vessels shown by the hyperæmia at the time of the operation. The pains were attributed to irritation of the cord or its membranes by the animal arterial blood, and were thought to be produced in a similar manner to those which accompany small-pox.

The operation was performed in each case at the desire of the patients, who, inspired by the thought that they had new blood in their veins, reported themselves much better the day after the operation; but the improvement was imaginary, and they soon were convinced that they had gained nothing. *The disease in the lung, as proved by physical examination, progressed steadily without interruption.* The appetite, weight, etc., were unimproved by the transfusion. In three cases it was succeeded by temporary hæmaturia, in one of which subsequent post-mortem section showed fatty degeneration of the kidney, of which there had been no symptoms prior to the transfusion. In a case of post-partum hemorrhage where it was resorted to, the patient showed at the autopsy a capillary hemorrhage into both pleural cavities, which was evidently caused by the transfusion, as there was no evidence of previous pleuritis. Two cases are on record where death occurred during the operation.

A case is reported where the transfusion of lamb's blood was resorted to in a case of anæmia produced by obstinate hæmatemesis. The usual physical disturbances occurred during the operation, from which, apparently, no relief was obtained, but the case appeared to be steadily progressing towards a fatal termination; when an unexpected change took place, and the patient (a girl of 22 years) rapidly and steadily recovered. This result cannot be credited to the transfusion, only in so far as it may have put off a fatal result until the change occurred, which was as unaccountable as it was unlooked for.

In a discussion before the Dresden Association, the physicians declared that they had been unable to prove any benefit whatever in tuberculous cases from transfusion with lamb's blood; indeed, in many of the cases

* Transfusion of Blood. Petersburg, 1873.

† Transfusion of Lamb's Blood into the Human Species. Petersburg, 1874.

the condition was much worse subsequent to the operation.

Nor do they regard it as productive of any possible good in cases of pyæmia or septicæmia. Drs. Fiedler and Birch-Hirschfeld do not regard the question of the utility of lamb's-blood transfusion as being settled conclusively, but as offering a fruitful field for future investigation. In the mean time, they express dissent from the opinion of Gesellius, that "lamb's-blood transfusion will inaugurate in medicine a new era,—the era of blood-giving,"—and think that from the present aspect of the question it will be much more likely to attain the title of "Ephemera" in medical history.

F. W.

ACTION PRODUCED UPON THE SKIN BY VARIOUS TRAUMATISMS.—Dr. Bloch publishes, in the *Archives de Physiologie*, January and March, a communication on this subject, giving the details of various experiments, and his conclusions therefrom, which are as follows:

1. Traumatism by pressure, frictions, percussion, feeble or violent, even followed by ecchymosis or hemorrhage, produce capillary congestion almost immediately.

2. The application of heated bodies has the same results.

The effects are different according to the sensibility of the integument; and at the same temperature gases produce the least impression, liquids the most.

Liquids themselves do not all burn at the same temperature.

Pure water seems to burn at the lowest temperature, the fats at the most elevated.

Greater or less facility of imbibition on the part of the epidermis is the principal cause of these differences.

3. The application of cold, whether it be brief or prolonged, whether the cold be moderate or violent, brings about dilatation of the smaller vessels and capillary congestion almost immediately.

4. The arrest of the entire circulation, or only of the venous, has, after it has ceased, the same result. It is, besides, a means of lowering the temperature, so far as the parts below the ligature are concerned, even if this only interrupts the venous circulation. The temperature of these parts rises, on the contrary, when the circulation has been re-established.

A. V. H.

FEVER AFTER TRANSFUSION.—Paul Liebrecht (*Centralblatt f. d. Med. Wissenschaften*, 1874, No. 37) has repeated the experiments of Profs. Albert and Stricker with regard to the influence of transfusion on the temperature of dogs. Direct transfusion from the femoral artery into the femoral vein of the same animal was performed, and the temperature measured in the rectum, the dog not being fastened for the performance of the experiments. In five of the cases there was no fever, but in the remaining four the temperature rose from one to two degrees. Two of these animals had been twice already the subjects of similar experiments without having had any fever. Simple ligature of the great vessels occasioned no fever, but after transfusion the temperature rose. Transfusion from the artery into the vein of the same animal can occasion fever. Liebrecht thinks that the phenomenon can be explained by increased pressure in the cava and a consequent congestion of the portal system.

W. A.

CURE OF SALIVARY FISTULA.—Dr. Prompt submitted to the examination of the Académie de Médecine, at a recent sitting, a child twelve years of age, on whom he had recently operated for salivary fistula with success. The history of the case was as follows. The patient, while descending a staircase, holding in the hand a *vase de nuit*, had fallen, and one or more fragments of

the vessel which had been shattered penetrated the cheek, causing a vertical wound, the superior extremity of which corresponded to the cartilages of the tragus, while the inferior limit was on a level with the median lines of the jaw.

Three days subsequent to the accident, saliva was observed escaping from the wound at a point corresponding to the course of the duct of Steno. Somewhat later, two other salivary fistulæ were found, but, while these latter closed spontaneously, the original one remained patulous. Under these circumstances Dr. P. performed, three weeks subsequent to the date of the accident, an operation, by means of a fine trocar introduced within the buccal cavity, and the new canal thus formed was kept open by tents until it became permanent. The fistulous opening was then closed by sutures, and a complete cure effected.—*L'Abeille Médicale*, September 7, 1874.

A. V. H.

STERILITY IN THE MALE RELIEVED BY THE OPERATION FOR CONGENITAL PHIMOSIS.—Dr. Paul Labarthe relates, in *L'Abeille Médicale*, August 31, a case coming under his notice of a young and apparently healthy married couple whose union, after a period of several years, remained unfruitful.

Examination of the wife showed no obstacle to conception, and at length the husband sought advice from Dr. L. as to whether the difficulty lay with him rather than with the lady.

Investigation of the genitals showed congenital phimosis, the preputial orifice being narrowed to such a degree that on the patient attempting to make water the entire cavity became filled and swollen with urine, which only escaped drop by drop from the almost pin-hole aperture of exit.

Dr. Labarthe proceeded to perform the operation for phimosis, which resulted favorably. The patient subsequently informed his physician that the semen, which in coition formerly had only escaped drop by drop, was now ejected in a normal manner. Shortly after, his wife became enceinte.

A. V. H.

RECENT RESEARCHES ON RECURRENT SENSIBILITY (*Gazette Hebdomadaire*, September 4).—MM. Arloing and Tripier publish the results of a number of experiments on resections of nerves recently performed by themselves. The object of these researches was to reproduce and interpret various known facts in relation to persistence of sensibility in the integument of the human hand after section of the median, radial, and cubital nerves. The existence of recurrent sensibility in the cutaneous nerves had already been demonstrated, as well as the fact that the influence of the sensory nerves extends beyond the zone of their distribution; and, finally, that persistence of sensibility in the peripheral portion of the divided nerve and persistence of sensation in the corresponding skin are connected phenomena, neither of which exists without the other. The experiments made by MM. Arloing and Tripier were not confined to the nerves of the upper extremity; those of the lower members were also examined, as well as the nerves of the face. It was found that where section was made at a point near the periphery, the various anastomosing branches above the point operated upon continued the sensibility of the part, while at a point much nearer the nerve-centres the anastomosis was wanting and recurrent sensibility was not observed. It would follow from this that in neuralgia the nearer the point of action of the morbid agent is to the periphery, the more widely spread would the painful sensation be, while the more closely such point of action approaches the nerve-centres, the less intense (other things being equal) will be the intensity and diffusion of the same sensation.

As regards indications for operative proceeding, the following points are suggested:

1. For motor nerves, or those supposed to be such, not only should the nerves in question be divided, but also the neighboring sensitive branches which surround them with recurrent nervous fibres.

2. For sensory-motor or sensory nerves it should particularly be sought to establish whether the trunks only, or also the branches, convey the morbid influence. In the former case, simple neurotomy would suffice to interrupt the transmission of such impressions; while in the latter case, recourse should constantly be had to associate sections, but in such a way as to interrupt the different paths of transmission, without producing any more disturbance (wounds) than is inseparable from the operation.

A. V. H.

TERTIARY SYPHILITIC AFFECTIONS OF THE TONGUE.

—Dr. M. Fournier, in a clinical lecture published in the *Gaz. Hebdom.*, September 11, remarks that the tongue, though less frequently attacked by tertiary syphilis than the pharynx or the velum palati, is yet often enough involved to give the study of these affections considerable interest. The study of these forms of syphilis has been retarded in the past from the fact that they have all been included under a single morbid type. This view of their nature is, however, incorrect, since the various lesions of the tongue are quite different, and correspond exactly to the cutaneous alterations of the same period. They may be divided into two classes,—one the non-ulcerative, including gummous nodules, the other, those which go on to rapid ulceration.

1. *Ulcerative syphilides of the tongue.*—Like the ulcerations of ecthyma, these are deep; having, also, raised borders, a yellowish-gray base, sometimes regularly rounded, as when seated upon the dorsum of the tongue, at other times irregular in outline, as found upon the edges or point. They are surrounded by a red areola, around the border of which the thickened mucous membrane presents a decided feeling of resistance. This lesion may be solitary, or the ulcers may be multiple, and grouped in a crescentic form; they are usually about the size of a lentil or haricot. In spite of their small size, they are frequently painful; less so in themselves than on account of the irritative contact of food, etc. It is hardly necessary to say that their evolution is chronic.

2. *Non-ulcerative, gummous syphilides.*—This variety consists in a dry induration of the lingual derm. It is the form designated by M. Ricord under the name of *plastic glossitis*. Clinically, these nodosities are characterized by their elevation, though slight, above the surface; they are less distinguishable by this feature, however, than by modifications presented by the mucous membrane in their neighborhood. This is unusually red, smooth, level, and without villousities, often looking as if the papillæ had disappeared. The nodosities are also quite appreciable to the touch from the feeling of resistance which they transmit to the finger, showing the mucous membrane to be thickened and dense,—in a word, infiltrated by a resistant neoplasm. One or more points may be affected, and the shape of the plaques may be either rounded or irregular. Occasionally the disease takes the form of a diffuse induration, affecting a considerable portion of the tongue.

3. *Gummata of the tongue.*—Gummata of the tongue may be divided, like those of the skin, into two classes, according to the locality in which they occur, whether in the mucous or submucous tissues. Again, like those of the skin, gummata of the tongue form tumors which, at first solid and non-inflammatory, become softened at a later period, break, and yield a discharge, assuming the appearance of open ulcers.

It is a curious fact that gummata of the tongue show

a marked predilection for the dorsum of that organ, usually occurring on the median line, more rarely upon the edges, and hardly ever upon the inferior surface.

Like the other syphilides above mentioned, gummata may occur either singly or to the number of three or four, which they seldom exceed, excepting when they take the rarely-found confluent form.

In appearance, gummata of the tongue present the aspect of shot or small almond-kernels beneath the surface; occasionally they are larger. When small, the form of the organ is not altered; but when the gummata are large or confluent, much deformity may exist. As the evolution of the tumor proceeds, it approaches the superior surface of the tongue, and begins to soften. At length it breaks, and, according to the account given by patients (for this phenomenon is never observed by the physician), gives exit to a yellow, purulent liquid, sometimes grumous and streaked with blood.

The physiognomy of the ulcerated gumma of the tongue is not pathognomonic, or at least not sufficiently so to aid much in the diagnosis. Its chief features are deep ulceration with excavation of the edges, hard, thick areola, and a cartilaginous base.

Under proper treatment this form of ulcer is rapidly healed, and leaves very little cicatrix, the mucous membranes, as is known, becoming renewed more easily than the skin. Prof. Fournier's favorite remedy in this class of cases is mercury in one of its various forms.

A. V. H.

THERAPEUTIC NOTES.

BROMIDE OF POTASSIUM IN THE TREATMENT OF MALIGNANT ULCERATING TUMORS.—M. Peyraud recommends the use of solutions of bromide of potassium, to be applied to malignant ulcers in the form of spray.

He maintains that it acts as a sedative upon the nerves, thus relieving pain, while at the same time it exerts a contracting effect upon the capillaries and a slight but beneficial caustic action on the general surface of the wound.

CATHARTIC ELECTUARY FOR USE IN THE LATER PERIOD OF DISEASES OF THE HEART.—

R Pulv. sennæ;
Pulv. jalapæ;
Pulv. scammonii;
Pulv. gambogiæ;
Mel. despumat.—M.

Sig.—Two to three tablespoonfuls every morning.

This formula is suggested by M. Peter in the later period of heart-disease, where there are multiplied visceral congestions, and where diuretics and drastics are indicated.

SULPHUROUS ACID AS A DRESSING FOR RECENT WOUNDS.—The following formula was used with great satisfaction in various parts of France during the late war:

R Acidi sulphurosi, f $\frac{3}{4}$ ss;
Aquæ, Oi.—M.

Apply in the form of lotion, or by means of an irrigator. This solution is particularly useful in wounds where there is much suppuration, or where cicatrization takes place slowly.

INTERSTITIAL INJECTIONS OF ACETIC ACID IN MUCOUS POLYPI OF THE PALATE.—A few drops of the ordinary acid are to be introduced daily into the tumor, by the aid of a hypodermic syringe. The pain is intense for a few moments, but soon subsides, and one or two weeks usually suffice for cure.—*Dr. Méplain, Trib. Médicale*, No. 307, 1874.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, OCTOBER 10, 1874.

EDITORIAL.

MEDICAL EDUCATION.

IF there is one thing more than another upon which the editorial wisdom of the *Philadelphia Medical Times* has come to a fixed conclusion, it is the worthlessness of the American system of medical education. If there is any one editorial purpose more definitely settled than another, it is that whatever of influence this journal may possess shall be used to aid in effecting a radical change in that system. Tersely, the method may be said to be a pitting of one college against the other in a race for students,—a race whose success often depends not so much upon the ability of the faculty to teach, and the opportunities afforded for study, as upon the ease with which the coveted M.D. is granted. The average American bows at the shrine of “getting on,” and to get on means to get money. Very often the medical student is poor, so that he is doubly spurred by his inborn genius for getting on and by the necessities of the case; he *must* have his diploma as soon as possible. Once the coveted parchment in his possession, he will trust to his wits and industry. And, to give him credit, his “wits” rarely fail him, for we honestly believe the great gift of Providence to this nation, or, to speak in the terms of the popular science of the day, the great product which the circumstances of races, life, and climate have evolved on this continent, is “wits.”

The professors’ emoluments depending upon the number of students, and the professor having the sole right of fixing the standard of attainment

necessary for graduation, the result must inevitably be a gradual cheapening of the bait. Medical education is in a bad enough state in the East, but in the West its condition seems to be worse. We hope we shall not offend the delicate sensibilities of any of our Western editorial brethren in saying this. It certainly cannot truthfully be denied that the colleges in that section have been underbidding one another in the matter of lecture-fees, until only forty, twenty-five, or even twenty dollars, instead of one hundred and forty dollars, are asked for a whole winter’s course.

When professors or faculties, for the sake of outstripping their competitors, strip themselves of that which is so dear to every man, a proper recompense for work, it is easy to perceive what will be the decision of questions concerning the requirements for graduation: the major, the good of self, usually embraces the minor, the good of others.

We are loath to believe that matters are so bad anywhere as is represented in the extract which we append to the present editorial; yet it is from the pen of one whose wounded honor has asserted that personal indignities alone can repay the insult offered to the West by the editor of this paper in stating that the Eastern medical centres contain more prominent men than the Western,—a fact which, we may state *en passant*, is due not to any intellectual difference between the men of the two regions, but simply to the same cause that occasions more corn to grow in crooked than in straight rows.

A gentleman so zealous for the honor of his section as is the author of the following extract surely cannot in any wise have exaggerated the imperfections that may exist in the institutions of his State. Yet what he says (*American Medical Weekly*, Sept. 29, 1874) is said of Louisville, the famous and ancient centre of medical teaching in the West,—a centre whose history is illumined by some of the most distinguished of American professional names:

“It were well that medical classes could assemble, and be taught, and be sent again to their longed-for homes without any other exhibition than that of harmony, without any other manifestations before them than those of dignity and self-respect. But this great desideratum, so much hoped for, so much sought, has not yet been attained. Sad is it to state what a regard for the truth compels the candid writer to declare: no sooner do the classes assemble than there begins that unworthy struggle for numerical success which at once characterizes, while it degrades, almost every city wherein medical students are congregated. Men calling themselves teachers discredibly struggle to swell the number of students in their respective colleges. In all cities it is censurable; in some, it is disgraceful in

the extreme. Each critic must write as he can truthfully write. In this city, the struggle mentioned is demoralizing and utterly disgraceful. No sooner does twilight mantle the streets in obscurity than men calling themselves teachers and gentlemen are seen coming out like shameless prostitutes and foul birds of the night seeking their prey. They may be seen in all the private boarding-houses and in the hotels of the city. Aliens to self-respect and decency, lost to all sense of shame, they have but one object: by deceptions and falsehoods, by unblushing effrontery and cowardly devices, to lure young men seeking this city for a medical education to their colleges."

What a pride we ought to feel in our most noble profession! What an inborn tenacity of honor it must have,—what an immensity of intrinsic respectability and high estate,—that, recruited by such means, entered through such portals, it can still magnify itself in the eyes of men!

DEATH OF DR. ANSTIE.

IN our last issue the death of Dr. F. E. Anstie, of London, was announced, but the cause of his death was mis-stated, owing to the incorrectness of the first statements of the London medical press. It appears that the doctor died of blood-poisoning, due to a dissecting-wound. Dr. Anstie pricked his finger with a needle whilst making an examination on Sunday, September 16, at Wandsworth, of the body of a child who had fallen a victim to the malignant epidemic in the investigation of the causes of which he had spent the morning, greatly exposed to sewer-gases. The wound was at once washed and sucked, but on Wednesday the doctor commenced to feel ill, and complained of pain in the right arm-pit. Chilly feelings later in the day became very prominent, and the pain and soreness of the arm increased very greatly. Thursday the patient was confined to his bed, and Mr. Brudenell Carter found him with a dry tongue, a dry, hot skin, and complaining of distressing headache and of much pain over the right pectoral region. During the day the symptoms increased in intensity. After a restless night the patient was still worse on Friday, and the assistance of Dr. George Johnson was obtained, who has since furnished the London *Lancet* with the following statement:

"I first saw Dr. Anstie with Mr. Brudenell Carter at 3 P.M. on Friday, the 11th inst. He was then delirious and quite unable to give a history of his illness. The tongue was dry; the temperature 105°; there was an erysipelatous blush about the size of the palm of the hand over the right pectoral muscle; there was excessive tenderness on pressure in the right axilla, and over

the front of the chest on the right side; the slightest movement of the arm elicited a cry of pain; there was no appearance of inflammation about the wound on the hand or up the arm. At half-past nine in the evening I again saw the patient, in consultation with Dr. Burdon Sanderson and Mr. Carter. His condition remained unchanged. At half-past nine on Saturday morning I again met Mr. Carter. We found the breathing was very rapid; there was a distinct friction-sound over the middle and lower lobe of the right lung, and dulness on percussion over the same space; the erysipelatous redness and the tenderness on pressure remained the same. The urine was highly albuminous, and contained numerous epithelial casts. About the middle of the day symptoms of a blood-clot at the right side of the heart came on; the features were livid; the breathing rapid and shallow; consciousness was rapidly lost, and death occurred at half-past 2 P.M."

No post-mortem was made.

Dr. Anstie was born in December, 1833, and was, consequently, not quite forty-one years old at the time of his death. He was just reaching that pecuniary success which follows in most cases what may be termed professional success. It is stated that some years since a very determined effort was made to induce his acceptance of a professorship in New York city.

ERRATUM.—By some unaccountable mistake, the production of the paper on carbolic acid, in a recent issue, was credited to Dr. W. H. Winslow, Baltimore. We do not know that there is a physician of that name in that city: certainly the paper was written by Dr. W. H. Winslow of this city.

CORRESPONDENCE.

ON THE USE OF BELLADONNA AND OF CHLORAL AND BROMIDE OF POTASSIUM IN ASTHMA.

BOSTON, September 26, 1874.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—Dr. Wood's experience as to the superior efficacy of belladonna as a remedy in spasmodic asthma, communicated to your valuable journal of the 19th inst., is quite in accordance with my own. May I take the liberty of adding that I find the most prompt and effectual way of administering it is inhalation by means of an atomizer? I was induced to try this method, some years since, in the case of Dr. Derby, the late lamented Secretary of the Board of Health of this State. When he consulted me he had been suffering for six weeks from attacks of spasmodic asthma, which compelled him to rise at about one o'clock A.M. and pass the rest of the night without sleep, by his furnace fire, smoking cigars. He had lost much flesh,

and was a good deal exhausted by the want of sleep. After trying various remedies without much relief, I suggested to him to inhale a mixture of a drachm of fluid extract of belladonna to an ounce of water, by means of an atomizer, as soon as the next attack began. I recommended the extract in preference to the tincture, as it is much stronger and appears to be more reliable. Dr. Derby, however, employed the tincture, and the very first experiment was a complete success. When he retired at night he placed his atomizer, with the belladonna-mixture, by his bedside, in readiness for the emergency. At one o'clock the paroxysm came, and he immediately had recourse to the atomizer. In fifteen minutes he was entirely relieved, and fell asleep, to awake again at six o'clock, with a light return of the asthma. A second inhalation relieved him in five minutes, and he fell asleep again. The next day I found him much refreshed and jubilant, feeling that the spell was broken. He had no recurrence of the asthma after that time, but felt that he had a certain remedy, should it ever return, in the belladonna-inhalation.

I ought to say that Dr. Derby had for many years been asthmatic, being one of the excessively susceptible class in whom a paroxysm is induced by the proximity of a cat or a dog, or even of a horse. During the late war, in which he served with great distinction, he told me that he could not inhale the breath of his horse, or handle him in any way, without oppressed breathing.

It seems to me that the inhalation of belladonna has a decided advantage over its administration by the mouth, in that it acts directly upon the affected parts at the same time that it enters the circulation more promptly through the mucous membrane of the lungs. Again, its use can be exactly guided by its effects. The inhalation can be stopped at once on the occurrence of any of the uncomfortable physiological symptoms which it is liable to cause; in other words, the dose can be limited to precisely the quantity needed to produce the desired effect.

At the time when Dr. Derby first employed it, examination of his chest showed universal strong resonance on percussion, very feeble respiratory sound, and very abundant fine sibilant râles,—a pure case of spasmodic asthma.

With regard to the use of chloral and bromide of potassium together as a sedative in these and other cases of chest-affection, I would say that I have repeatedly used this combination, and I dare say it has occurred to many others to employ it. During the present autumn, some of my patients who are victims of "autumnal catarrh" have found great comfort from it. The addition of a little morphia adds to its efficacy, and in one instance at least, that of a lady who is very susceptible to the disagreeable after-effects which opiates so often produce, the chloral and bromide seem to prevent their occurrence entirely.

Very respectfully,

Your obedient servant,

S. L. ABBOT, M.D.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, SEPT. 10, 1874.

THE PRESIDENT, DR. WM. PEPPER, in the chair.

THE Chairman of the Committee on Morbid Growths, Dr. R. M. BERTOLET, read the following reports:

"1. *Report on the button-like prominence upon the inner wall of the cavity, presented by Dr. Pepper, June 25, 1874.*—This has been hardened and sections made. The central portion of the node is occupied by a firmly coagulated blood-clot, while the thick limiting membrane is made up of a layer of fibrinous connective tissue, succeeded by a stout layer of non-striated muscular fibres arranged in longitudinal and transverse rows; thus at once suggesting the middle and outer coats of an artery. No traces of the tunica intima are discernible, nor could any communication with the lumen of the blood-vessels beyond be satisfactorily established. Your committee are undecided whether to regard this prominence as an aneurismal dilatation, or as the stump of a larger artery formerly traversing the vomica and now filled with an embolus. In either case it probably proved the source of the fatal hemorrhage.

"2. *Supra-renal capsules, presented by Dr. F. P. Henry, June 25.*—The microscopical examination of the enlarged supra-renal capsules accompanying Dr. F. P. Henry's specimens from a case of Addison's disease exhibits an excessive development of the stroma into fibrillated connective tissue, which is marked with small-cell infiltration. At numerous points large cheesy foci, composed of granular detritus, are seen in varying degrees of softening. No miliary tubercles were detected. There is almost complete destruction of the parenchymatous glandular structure; though towards the cortex long parallel cell-columns are found at great intervals.

"We have here to deal with that alteration of the supra-renal capsules most frequently observed in morbus Addisonii,—viz., *cheesy fibrinous metamorphosis* of these glands. It may be here remarked that this cheesy fibrinous degeneration is very liable to be associated with tubercles in these glands themselves, or else it is complicated with general tuberculosis. According to Klebs, this association of the two diseases occurs about in the proportion of two to one.

"3. *Cystic kidney, presented by Dr. Willard, June 25.*—The cystic kidney presented at the last meeting has been examined by your committee; the thick walls of the cysts are made up of a dense, fibrillated basement-membrane, and are lined upon the inner surface with flat polygonal epithelial cells. The surrounding uriniferous tubules are greatly displaced, often entirely obliterated, by the excessive proliferation of the interstitial connective tissue; their epithelial covering is seen in the various stages of fatty infiltration and disintegration, while their lumen is not infrequently occupied by fibrinous cylinders; here and there, however, traces of a secreting parenchyma are visible.

"As to the soft, cheesy, white mass contained in the large cystic cavity of the cortical substance, it is found to be made up in greater part of fat- and pigment-granules, of epithelial detritus, colossal cholesterolin tablets, and amorphous granular matter; the latter, consisting of carbonate of lime and a colloid substance, yielding the albuminoid reactions. It contains no uric acid or other crystalline products of the urine."

Patulous foramen ovale, and thickened and attached pericardium.—Dr. WHARTON SINKLER presented the specimen, from Mrs. L., æt. 60, who was admitted to

the medical wards of the Episcopal Hospital, February 18, 1874. She was suffering from dyspnoea, anasarca, and showed a constant disposition to sleep. The circulation was sluggish, and a general venous turgescence existed. The urine contained albumen. The patient died July 28. At the autopsy the kidneys exhibited the characters of the contracted granular kidney. The lungs were healthy. The pericardium was firmly attached to the heart throughout, and was thickened. There was a communication between the auricles through a patulous foramen ovale. The opening was valvular, and it is not likely that during life there was any passage of blood from one auricle.

Hypertrophy of the heart; pericarditis, with enormous thickening of the pericardium.—Dr. SINKLER presented the specimen, from A. B., admitted to the Episcopal Hospital July 8, 1874. He complained of pain in the back and around the base of the chest. There was no tenderness over the liver, but the area of hepatic dullness was lessened. There were anorexia, nausea, and at times diarrhoea. The emaciation was extreme, but there was no dropsy. Patient acknowledged to having been a hard drinker of undiluted spirits. There was no cardiac murmur detected, and the heart's impulse did not appear to be increased. A diagnosis of cirrhosis of the liver was made. He gradually lost strength, and a few days before death the gastric derangement increased and there was some diarrhoea.

On August 26 he was confined to his bed, and complained of weakness. On the 28th he was delirious, stupid, and disposed to sleep. He refused all food except small quantities of punch. The symptoms increased in severity, and death supervened on September 4, the patient having been comatose for forty-eight hours previous.

The *post-mortem* was made five hours after death. The *lungs* were firmly attached to the walls of the thorax by old adhesions, and there were scattered tubercles throughout both. The *kidneys* were large, but appeared healthy. The *heart* was hypertrophied. The *pericardium* was attached to the lungs. Both layers of pericardium were greatly thickened, and presented the appearance of fatty degeneration. Binding these layers strongly together was a thick deposit resembling a partially organized clot, of a reddish color and of firm consistence. The thickness of the pericardium, including the deposit of new tissue, was five-eighths of an inch. The left ventricle was three-fourths of an inch, and the right one-half inch thick. The length of the heart was seven inches, and its greatest circumference ten and a half inches. The liver was somewhat contracted, and was a well-marked specimen of cirrhosis.

Extensive disease of mitral valves; auricular vegetation.—Dr. SINKLER also presented this specimen, from Maggie L., æt. 16, who was admitted to the Episcopal Hospital January 13, 1874. She had suffered from a severe attack of acute articular rheumatism, and on admission had violent dyspnoea on the slightest exertion. There was a dry cough. The heart was hypertrophied, and an unusually loud murmur was heard all over the præcordia, with the systole and diastole. The murmur was loudest at the apex, and was heard with distinctness at the inferior angle of the scapula. It diminished in intensity towards the sternum.

On August 24 she had another attack of articular rheumatism, and complained of pain in the præcordia. Death occurred on the 30th.

On *post-mortem* the left lung was found bound down by old adhesions, and there was a tubercular deposit at the apex. The pericardial sac was obliterated by a recent formation of lymph. The tricuspid valves were partially adherent. The leaflets of the mitral valve were thickly covered with vegetations of a calcareous nature, and extending into the left auricle were exten-

sive villous vegetations, the lower half of the anterior surface of the endocardium being covered by the vegetations. Aortic valves healthy.

The PRESIDENT said that there were two or three points of interest in connection with these cases constituting the group an extraordinary one. Two of the cases exhibited universally adherent pericardium, and in another the pericardium was partially adherent. Universal adhesion of the pericardium is of itself a comparatively rare affection. In one of the specimens the appearances indicated the presence of the rare form of pericarditis known as "hæmorrhagica." Before pronouncing positively upon the nature of the clot-like layer which invests the body of the heart, he would refer the specimen to the Committee on Morbid Growths.

Another point was the occurrence of vegetations on the auricular endocardium, quite independent of the valves, —a condition rarely met. The question of presystolic murmurs has attracted so much attention of late years that the presence of the vegetations becomes of double interest. He thought it highly probable that a considerable portion of the murmur in this case depended upon these vegetations. A third point of interest was the fact that a patulous foramen ovale should be presented in a person of such advanced age as sixty. Dr. P. agreed, however, with Dr. Sinkler in attributing no great practical significance to this lesion. Several years ago he made several hundred examinations of the condition of the heart, noting carefully in each instance the condition of this foramen. In a considerable proportion of cases he had found it patulous in persons of advanced years, occasionally with, but as often without, coincident heart-disease.

Dr. J. EWING MEARS asked whether in those cases of patulous foramen which attended heart-disease there was any relation between the two.

The PRESIDENT replied that when he had found this condition present in cases of heart-disease it had seemed to be usually associated with one of two conditions: 1, excessive dilatation of the auricular cavities, when the opening in the valve might be caused by atrophy due to excessive stretching, just as small perforations are found near the free border of the aortic valves in cases of great dilatation of the orifice of that vessel; or, 2, an excessive degree of intra-cardiac tension, due to obstructive valvular disease, and operating unequally on the cavities of the right and left sides of the heart, in which case the strain might cause a separation of the valve of the foramen at its point of weakest attachment. In still other cases, a small opening in the valve might persist from infancy.

The thickened blood-stained pericardium was referred to the Committee on Morbid Growths, which reported September 24, 1874:

"The thick pericardial covering upon the heart, presented by Dr. Sinkler, is composed of laminæ of corpuscular elements (leucocytes) enclosed in the meshes of the interlacing, delicate fibres of organized fibrin. This covering is therefore to be regarded as an inflammatory product."

Tumor involving the parotid gland and masseter muscle.—Dr. J. EWING MEARS presented the specimen, which he had removed from a male patient, aged 58, at St. Mary's Hospital. A description of the specimen will appear in a forthcoming number of the *Medical Times*. It was referred to the Committee on Morbid Growths, which reported September 24, 1874:

"The large tumor removed from the parotid region on September 10, by Dr. Mears, is made up of large round and spindle-cell elements; the sparse interstitial substance is finely fibrillated.

"Some of the sections reveal the presence of a glandular tissue and ducts lined with cylindrical epithelium, thus leaving little doubt of the involvement of the paro-

tid gland. There is apparently no excessive development of the epithelial lining, no budding out of epithelial processes; but, on the other hand, the glandular cells are widely separated and compressed by the abundant development of the sarcomatous cells in the connective tissue.

"The sarcoma has likewise invaded the masseter muscle, and here it also seems to spread along the connective tissue mainly, though in a few of the muscular fibres beneath the sarcolemma were seen extending the large nucleated bodies, as if the sarcomatous elements were undergoing a similar transformation.

"Further study of these sections will, however, be requisite before your committee can pronounce with any degree of certainty on this point. Many of the muscular fibres are irregular in outline, swollen and contorted; their striations are obliterated, a so-called 'amyloid degeneration' having taken place. This condition has often been noted in muscular fibres that are being encroached upon by new growths."

Osteo-sarcoma of the lower jaw, involving the ramus, angle, and a portion of the body.—Dr. MEARS presented the specimen, which he had removed from a boy, æt. 14. A description will appear in a forthcoming number of the *Medical Times*.

Dr. MEARS further said that in this case the diagnosis was sarcoma, the jaw presenting the stony hardness of such growths. But the diagnosis in this situation is at all times difficult. Where the lymphatics over the parotid are the seats of disease, the movability of the growth aids a decision. Last summer he had removed a tumor, as large as a Sicily orange, from directly over the parotid, and he was confident that it did not involve the gland, from this circumstance.

The PRESIDENT asked whether the degree to which the mouth could be opened could be of assistance in the diagnosis of these cases.

Dr. MEARS said that in the last case there was almost entire occlusion: it being possible only to introduce the handle of a scalpel between the teeth. He had thought the occlusion due, in these cases, to an involvement of the masseter muscle.

The PRESIDENT replied that the question had been suggested by the fact of the extreme occlusion which attends the implication of the parotid in medical cases. He thought it might be possible to draw an inference as to site of growth from the presence or absence of this difficulty. A tumor of the periosteum, for example, we would primarily suppose less likely to prevent opening of the jaws than one more directly involving the parotid or the muscles.

The specimen was referred to the Committee on Morbid Growths, which reported, September 24, 1874:

"The series of small tumors removed by Dr. Mears from a patient æt. 14 present, as suspected, the well-known microscopic appearances of the round-cell sarcoma; but only in such a subordinate manner that your committee, in making this their preliminary report, are inclined to view it as a mere sarcomatous degeneration of the striated muscular fibres which make up the bulk of the growth,—in short, are seen in sections made in every possible direction. Should this prove, upon further investigation, to be the case, then it must be pronounced a *myosarcoma*."

REVIEWS AND BOOK NOTICES.

ESSENTIALS OF THE PRINCIPLES AND PRACTICE OF MEDICINE. By HENRY HARTSHORNE, M.D. Fourth Edition. H. C. Lea, Philadelphia, 1874.

A book which reaches its fourth edition in seven years certainly may be looked upon as a pecuniary

success,—a success which the present volume has deserved, in that it is the best of its class,—albeit that class is, to our thinking, of doubtful value.

SELECTIONS.

CASE OF FATAL POISONING BY AN OVER-DOSE OF GELSEMINUM SEMPERVIRENS.

AUGUST 20, 1874, Frank R., æt. 24, took for neuralgia, at 1 o'clock A.M., a teaspoonful of Tilden's fluid extract of gelseminum, and in about fifteen minutes repeated the dose. The pain was soon relieved, and his eyes felt heavy, but in about half an hour he began to complain of choking, and soon arose struggling for breath, pushing his fingers into his throat as if trying to tear it open. He staggered, reeling from one room to another as though intoxicated, and in a short time after these symptoms came on he threw himself upon the floor and became unconscious. This is the history of the case as I received it from his family.

I was summoned about 3.45 A.M., and reached the house at 4 A.M. Found patient moribund, respiration gasping, three or four per minute, pulse rapid and feeble. He was totally unconscious, and could not be roused; pupils dilated, not responding to light, and could be touched without producing any contraction of the lids. Muscles relaxed, lower jaw drooping. Skin moist, extremities rather cold.

As the patient was so far gone, as the dose had been swallowed three hours before and was probably all absorbed, and as there was such complete insensibility, I considered it useless to try emetics. I laid him upon his back with head upon floor, dashed cold water upon face and chest to excite respiration. Gave brandy-and-water in small quantities frequently, and five grains of carbonate of ammonia every five minutes. Mustard to spine, and friction upon extremities. The respirations became more infrequent, and the pulse grew slower and weaker. Artificial respiration was kept up for half an hour, but without avail, and he died at 4.45 A.M. No convulsions at any time.

Autopsy, five and a half hours after death.—Body well nourished, rigor mortis well marked. The blood was very fluid and dark-colored, and showed no tendency to coagulate or to turn red upon exposure to the air, even after standing in a large tub for two hours. Heart, lungs, spleen, kidneys, normal. Liver dark-colored, and contained much fluid blood. Stomach contained four ounces of light-colored fluid mixed with glairy mucus. Its internal surface was deeply congested, and marked by tortuous dilated vessels. Intestines normal. Brain rather pale. Sinuses not congested. The internal substance of the cerebral lobes was dotted here and there with small red points, but these were not sufficiently large or numerous to be considered of much pathological importance. No collection of fluid in ventricles.—*J. T. Boutelle, M.D., in Boston Medical and Surgical Journal.*

ICE IN PAINFUL CONDITIONS OF THE BLADDER AND RECTUM (*The Chicago Medical Journal*, September, 1874).—Dr. Henry M. Lyman reports cases of internal piles, irritable bladder, recto-vaginal abscess, and vesical irritation, caused by cantharidal poisoning, in all of which great and immediate relief was obtained by the employment of ice suppositories either in the rectum or vagina; and when their use was persevered in, a complete cure resulted.

GLEANINGS FROM OUR EXCHANGES.

IPECACUANHA SPRAY IN WINTER COUGH AND BRONCHITIC ASTHMA (*The Lancet*, September 5, 1874).—Drs. Sydney Ringer and William Murrell have obtained excellent results from the use of ipecacuanha-spray in winter cough, a typical case of which disease they describe as follows:

The patient has been troubled with winter cough perhaps for many years. During the summer he is pretty well; but during the cold months, from October to May, he suffers sometimes without intermission, occasionally getting a little better, and then catching cold; or perhaps he may lose his cough for a few weeks, but again takes cold on the slightest exposure. So short is the breathing that he can walk only a few yards, especially in the cold air, and finds it hard work to get up-stairs, and is often quite unfitted for active life. The breathing grows worse at night, so that he cannot sleep unless the head is propped up with several pillows. He is troubled, too, with paroxysmal dyspnoea, usually at night, which may last several hours, and compels him to sit up. Sometimes the breathing is difficult only on exertion; and in those cases it is made much worse by fogs, east winds, or damp. The expectoration varies greatly: in a few cases there is very little; usually, however, it is rather abundant, and consists of mucus or pus, often with little or no rhonchus in the chest. It is often difficult to expel the expectoration. The cough is generally very violent, frequent, hacking, and paroxysmal, and the fits may last ten or twenty minutes, and even excite vomiting. They are generally brought on by exertion; nay, in bad cases so easily are they provoked that the patient is afraid to move, or even to speak. The cough and expectoration are much worse in the morning on waking. Sometimes the cough is slight, and then the expectoration is generally scanty, the distressed breathing being the chief symptom. The patient generally wheezes badly, especially at night, and in a bad case the legs are swollen. The patient is emphysematous; there is often no rhonchus, or only sonorous and sibilant or a little bubbling rhonchus at both bases.

In such cases the ordinary spray-producer was used, with ipecacuanha wine pure or variously diluted. On the first application it sometimes excites a paroxysm of coughing, which generally soon subsides, but if it continues, a weaker solution should be used. The patient soon becomes accustomed to it, and inhales the spray freely into the lungs. At first a patient inhales less adroitly than he learns to do afterwards, as he is apt to arch his tongue so that it touches the soft palate, and consequently less enters the chest than when the tongue is depressed. The spray may produce dryness or roughness of the throat, with a raw, sore sensation beneath the sternum, and sometimes it causes hoarseness; whilst, on the contrary, some hoarse patients recover voice with the first inhalation. As they go on with the inhalation, they feel it getting lower and lower into the chest, till many say they can feel it as low as the ensiform cartilage.

The dyspnoea is the first symptom relieved; but soon the cough and expectoration are lessened, and then disappear. The inhalation should be used at first daily, and in bad cases twice or thrice in the day; afterwards, every other day suffices, and the interval may be gradually extended. If the ipecacuanha wine is diluted, then the spray must be used a longer time. In cold weather the wine should be warmed.

All but one of twenty-five patients were benefited. In one case the improvement was very gradual, but there was evident temporary improvement after each inhalation. In twenty-one cases the average number of inhalations required was 9.4, and the average num-

ber of days was twelve, before the patients were discharged, cured. The greatest number of inhalations in one case was eighteen, and the smallest three. The case longest under treatment required twenty-four days; the shortest, four.

In bronchial asthma very satisfactory results have been obtained by the same means.

DETERMINATION OF THE SEX IN UTERO (*Chicago Medical Journal*, September, 1874).—As the result of observations in fifty obstetrical cases, Dr. D. A. K. Steele has come to the following conclusions:

1. In the majority of cases *male* foetal hearts are slower than *female*.

2. 132 foetal pulsations per minute is the average dividing line. Below this, 68½ per cent. are male; 20 per cent. female; 11½ per cent. doubtful. Above this, 53½ per cent. are female; 26½ per cent. male; 20 per cent. doubtful.

3. The most accurate observations are made during the last four weeks of gestation.

4. The rapidity of the heart's action is increased in proportion to the feebleness of the foetus.

5. Calcareous or fatty degeneration of the placenta renders the pulsations feeble and irregular.

6. In some cases it would be possible to diagnose diseased conditions of the placenta from careful observation of the foetal heart.

The sounds of the foetal heart may be rendered feeble by thick abdominal walls, tense abdominal muscles, or the presence of a large quantity of amniotic fluid.

The attachment of the placenta may be determined by the souffle, a soft blowing murmur, synchronous with the maternal heart-beat.

The weight of the child does not increase the force of the foetal heart. During labor the foetal heart becomes accelerated and irregular in its action. The most accurate diagnosis was the result of repeated observations, as the foetal heart might be accelerated in its action by temporary excitement during a single examination.

LOCAL POISONING BY LEAD.—Dr. A. Manouvriez, having inquired into the experience of thirty workmen who from the nature of their occupations were brought more or less into contact with lead, has come to the conclusion that possibly all the local symptoms of paralysis, change of sensibility, etc., are the result of the direct absorption of the poison through the skin. In those who were right-handed, it was always the right upper extremity that was affected; while in the left-handed the symptoms were, for the most part, confined to the left upper extremity. A worker in white-lead, whose feet were most frequently brought into play (in the process of stamping), was first affected in these parts. Two right-handed workmen happened to be seized with paralysis in the left arms and hands, but in their case it transpired that it was the left upper extremity which had come in contact with the lead.

In view of these observations, we are justified in asserting that by applying an artificial protection to the skin of lead-workers we may be able to afford an efficient prophylactic against lead-poisoning.—*Gaz. des Hôpitaux*, May 7, 1874.—*Boston Medical and Surgical Journal*.

ARTIFICIAL PRODUCTION OF DIABETES (*The Lancet*, August 29, 1874).—Dr. Pavy has found that the injection of defibrinated arterial blood into the portal system occasions a saccharine state of the urine. In one experiment, the urine after the operation contained fifteen grains of sugar to the fluidounce, and in others the quantity has amounted to nearly the same. In the counterpart experiment of injecting defibrinated venous

blood into the portal system, the urine showed no signs of the presence of sugar. It thus appears that oxygenated blood passing to the liver causes an escape of sugar from the organ, and thence an accumulation in the system and discharge with the urine. It also appears that through the medium of the respiration of oxygen he has succeeded in inducing a sufficiently oxygenated state of the blood to similarly give rise to the production of saccharine urine. He has further found that through the agency of the inhalation of puff-ball smoke an immediate and strongly diabetic state may be induced, and that the effect is accompanied with such a modification of the circulation that the blood flows through the vessels, as is the case after section of the sympathetic, without becoming properly de-arterialized. His experiments, he considers, suggest that, in diabetes of the human subject, the blood, in consequence of vaso-muscular paralysis, is allowed to reach the portal vein in an imperfectly de-arterialized condition, and thus determines the escape of sugar from the liver.

PARALYSIS AGITANS (*The Dublin Medical Journal*, July, 1874).—Mr. Rankin reports a case of paralysis agitans, occurring in a man aged 72, by occupation a carpenter, who had first been affected with bronchitis, and then complained of great and increasing tremor in both hands and arms. This lasted for some time, so that he could not even lift a cup of water to his mouth. Tonics were tried, and improved the general health, but had no effect on the shaking. Hypodermic injections were then commenced of five minims of a solution of equal parts of water and the liquor arsenicalis, and were given every second day. After the third injection the patient was able to lift a tumblerful of water to his mouth, and could close both his hands without tremor. He complained, after the second injection, of tenderness of the conjunctiva of both eyes, showing that the arsenic was beginning rapidly to take effect. He was soon able to resume his ordinary work.

CO-DEVELOPMENT OF INTRA- AND EXTRA-UTERINE PREGNANCY (*St. Louis Medical and Surgical Journal*, August, 1874).—Dr. John T. Hodgson reports the case of a healthy female, æt. 27, in whom the early symptoms of pregnancy were attended by the development of a sensitive tumor within the pelvis, and to the left of the uterus, and which enlarged at the same time with the latter. For two months she had great pain in the pelvic region, with nausea and vomiting, and grew very weak. At the end of that time both the uterus and tumor had arisen out of the pelvis, and the outline of the right enlargement could be distinctly traced as continuous with the neck of the uterus, while the tumor to the left, though closely pressed against the other, was distinct.

It then ceased to enlarge, and gradually diminished in size, but remained tender to pressure, and in a month or two presented some irregularities in form, that had not before been observed.

At the proper period the woman was delivered of a healthy living child, the tumor having decreased until it was no larger than a lemon. A year later it was about the same size, somewhat irregular, a little sensitive to touch, moving freely with the uterus, lying higher in the pelvis than that organ and pushing it to the right. The case was believed to be one of tubal pregnancy, in which the sac burst about the fifth month without much hemorrhage; the fœtus died, and a limited peritonitis occurred.

MUSHROOM-POISONING (*The Cincinnati Lancet and Observer*, October, 1874).—Dr. D. B. Jackson reports three cases of poisoning occurring in children aged respectively eight, ten, and twelve. About fifteen minutes

after eating some mushrooms they all vomited, and then became sleepy and stupid. The younger two were purged somewhat; the eldest had one convulsion. They all went to sleep in a few moments, and when seen two or three hours later lay unconscious, with upturned eyes, swollen faces, and coated tongues. Reflex action was abolished, and the ability to swallow was almost gone. Tannin was given as an antidote, with an emetic of sulphate of zinc, strong tea in large quantities, compulsory exercise, and cold douches to the head and spine. These remedies were persevered in for about three hours, when the narcotism disappeared and the patients were found to be out of danger.

NOTES AND QUERIES.

WE have been asked to give room to the subjoined notice, and in doing so take occasion to remind our city readers that the Academy is at present in great need of a few thousand dollars to enable it to roof in its new building. It would be a disgrace to our city if this should not be obtained; and as many of the Philadelphia naturalists have been among the brightest lights of our profession, we, as physicians, ought to be doubly interested in the matter. The smallest contributions will be acceptable, and may be sent to Dr. W. S. W. Ruschenberger, hall of the Academy. Some who cannot themselves give may be able to obtain one or more subscriptions from their friends or patients.

ACADEMY OF NATURAL SCIENCES OF PHILADELPHIA.—The matriculants of all medical schools established in Philadelphia are admitted to the museum of the Academy of Natural Sciences of Philadelphia on exhibiting their matriculating tickets at the door.

"The museum is open on Tuesdays and Fridays, from ten o'clock A.M. till sunset."

A NEW CHARITY has been started in this city, under the name of the Gynecological Hospital and Infirmary for Diseases of Children. The title sufficiently indicates its object. The corporators are John Pearce, James Moore, John J. Reese, William S. Reyburn, D. Hayes Agnew, Thomas Dolan, John Robbins, J. A. McFerran, Theo. H. Seyfert, M. Simpson, L. P. Hornberger, Joseph Singerly, Dilwyn Parrish, and S. Flanagan.

OBITUARY.

DR. WASHINGTON ATLEE HOFFMAN, Physician to the City and Port of Philadelphia, whose death has already been announced in the *Times*, was a graduate of Amherst College, in the class of 1864, studied medicine and languages at the University of Göttingen for about two years, and graduated in medicine at the University of Pennsylvania in the class of 1868. Shortly after his graduation he was elected one of the Resident Physicians to the Philadelphia Hospital (Blockley). Since the expiration of his term of service at that institution, although only thirty years of age at the time of his death, he has held various public positions, among which were Physician to the Charity Hospital and Physician to the German Hospital, to which position he was elected only a few days before his death. He was appointed by the late Governor Geary Surgeon-in-Chief, with the rank of Major, of the First Brigade, under the command of General Bankson, and in January, 1873, he was appointed Port-Physician by Governor Hartranft.

Dr. Hoffman's social qualities, his uniform courtesy, his unremitting attention to his duties, and his unimpeachable integrity, peculiarly fitted him to fill positions of public trust, while his fidelity to the honor of the high calling which he had chosen won for him the universal regard and esteem of his professional brethren.

THE first conversational meeting of the Philadelphia County Medical Society for the season will be held at 8 P.M. on the evening of October 14. A large attendance is requested, as the subject of the Society's publications is to be decided.

SATURDAY, OCTOBER 17, 1874.

ORIGINAL LECTURES.

CLINICAL LECTURE ON THE DIAGNOSIS OF THE DISEASES OF WOMEN.

BY F. H. GETCHELL, M.D.,

Clinical Lecturer on the Diseases of Women in the Jefferson Medical College.

GENTLEMEN,—When Demosthenes was asked what was the first part of oratory, he answered, delivery; and the second—delivery; and the third—delivery; and I think we may safely say that the first object to be obtained by the study of gynæcology is diagnosis; and the second, diagnosis; and the third, diagnosis. To be sure, we are not to stop here; but after a correct diagnosis has been made the case is plain, and without it there will be no success either in prognosis or treatment. The diagnosis of uterine disease is not or ought not to be very difficult, and still one who devotes much time and attention to the study of the diseases of females is constantly meeting with cases where an incorrect diagnosis or no diagnosis at all has been made.

Now, why is this? The modes of examination are numerous, and the directions how to proceed are plainly given in the text-books. The reason is not that the means of diagnosis have failed to clear away the obscurities of the case, but that the practitioner has failed to make use of them, and after the most superficial examination, from which he has no right to expect to learn anything, he concludes either that he knows all about it, or that he doesn't know anything about it, as the case may be; and the result, so far as the recovery of the patient is concerned, is the same either way. My experience coincides with that of Dr. Thomas, who says, "I have been struck by the fact that the source of difficulty is almost always the same. The failure of diagnosis has not been due to their having incorrect conclusions from diagnostic means, but to their not having brought these means fully into action, and properly applied them to the solution of the case in hand." If we are to obtain information that will be of any value to us in the treatment of these cases, our examination must be systematic and thorough. It is time that the asking a few irrelevant questions, the hurried introduction of a speculum, and the whitening the os with nitrate of silver, were done away with. The art of observing, which has been called the alphabet of diagnosis, while it is within the reach of those resolved on its attainment, and is sure to be acquired by those who systematically and patiently cultivate the habit of close observation, is by no means so easy to acquire as you may suppose. You must remember that it is not the amount of disease that passes under the physician's observation that gives him knowledge; one man will learn more from one case than another will from a hundred, by close observation. I mean that love of investigation that

allows nothing, however insignificant, to escape it; the minutest details are observed and recorded; and here let me say to you that perhaps there is nothing that retards the advancement of young physicians more than contempt for minutiae. They are so apt to forget that those who achieve the grandest results are the men who allow nothing to escape their notice. It is told of Wellington that on the publication of his "Dispatches," one of his friends said to him, on reading the records of his Indian campaigns, "It seems to me, duke, that your chief business in India was to procure rice and bullocks." "And so it was," replied Wellington; "for if I had rice and bullocks I had men; and if I had men I knew I could beat the enemy."

You have observed at this clinic that we make it a rule to allow the patient to tell her own story without interruption; and though it is sometimes tedious, and we are obliged to listen to much that has no bearing upon the case, still there is among the chaff now and then a grain of wheat that can be found in no other way, and without which the history of the case would be incomplete.

The patient having concluded her account of her illness, it is now our turn to ask such questions as we think requisite.

Time and practice are required to acquire skill in the cross-examination of patients; and when you remember how our friends the lawyers are obliged to practise the cross-questioning of witnesses before they become skilful examiners, you will not give up trying to improve, or be discouraged at your early failures. It is not often that the patient intentionally misleads the physician, but she may be embarrassed and confused, or, from extreme modesty, only half answer the questions; there is a *suppressio veri*, although there is no *allegatio falsi*; but by relieving her embarrassment by looking away from, instead of at, her, and so wording the inquiry that she shall understand your meaning and at the same time see that you are regarding her feelings, you will gain her confidence, and learn all that is requisite in regard to her ailment. It is important that you follow some regular system in your examinations of the patient. You may adopt whatever method you please, only so you have a method,—a place to begin, and know when you have gone over the whole ground. You have noticed that I divide the examination into functional, constitutional, and local: under the first head I inquire as to the frequency and character of the menstruation, number of pregnancies and abortions, and character of her labors; under the second, with regard to the sympathetic disturbances so commonly associated with disease of the womb, the condition of the digestive function; whether she has headache, palpitation of the heart, and in regard to the condition of all the organs remote from the uterus; and under the third, the locality and character of the pains in the pelvic region, the condition of the bladder, amount and character of vaginal discharge, if any. Having learned all you can by questioning your patient, you are now ready to make a physical examination. We will suppose, then, that the patient has been placed upon a firm

unyielding surface before a good light, that she is covered with a large sheet, her lower limbs flexed, and the knees allowed to fall well apart. You are now ready to do—what? introduce the speculum? No. That is what is too often done, and is just what you are not to do if you ever expect to become skilful in the diagnosis of uterine disease. It is not as a diagnostic but as a therapeutic instrument that you will find the speculum of the most service to you; but you have a diagnostic instrument, if I may use the term, in the index-finger of your right hand, worth more than any speculum that was ever invented. What I particularly desire to impress upon you is that at this stage of the examination there is nothing to be done with the speculum, and to call your attention to the importance of the much-neglected finger. After you have concluded the digital examination you may introduce the speculum, and look through it to verify the diagnosis you have made with the finger, so far as it relates to the os uteri; but not until a thorough digital examination has been made is the speculum to be thought of. Why, in fact, you don't even know what direction to give the instrument till you have ascertained the locality of the os with the finger; and then again you may do irreparable mischief. The worst case of hemorrhage from cancer of the womb I ever saw was caused by the introduction and expansion of the blades of a bivalve speculum, when a digital examination would have convinced the operator that it should not have been used. I dwell upon this point, gentlemen, even at the risk of being tedious, for I know from long experience that too much reliance is placed upon the speculum as an aid to diagnosis, and that a thorough examination with the finger is too often neglected. On the ticket issued by the late Prof. Mott, of New York, to the students attending his lectures on surgery, there was a hand with the index-finger extended, and in the end of that finger there was an eye; the meaning of which was that the student should so educate his finger that when occasion required him to pass it beneath the skin, he could see with it all that was there; and I am sure that in the diagnosis of the sexual diseases of females you will find nothing more important than the education and use of the finger, and by education I mean what I say. To be sure, it will take time for you to become skilful; but what do you think of the professional pianist who begins his studies with the understanding that he must practise four hours a day for eight or ten years before he can acquire that delicacy of touch that will rank him with first-class performers?—and, as an evidence of the extent to which the finger may be educated, we have seen the blind able to detect and map out the colors of a dress by the sense of feeling alone.

It may be that some of you think I overestimate the value of the finger in the diagnosis of uterine disease. Let us go on with our examination, and see what we can learn by its use. First, we will wash our hands, for we should always before touching the sensitive mucous membrane of any patient be sure that the hands are free from impurity; then we will smear with lard or oil the first two fingers, for you can reach about an inch higher with the

first and second than you can with the index-finger alone, and you will want to use both if you are not able to thoroughly explore the parts with one. We will take a seat before the patient, for considerable time may be occupied, and standing is tiresome. The vaginal canal being pervious, and the finger meeting with no obstructions, the first thing to be determined is the location of the os. Is it in the normal position of a healthy uterus, or is it low in the pelvic cavity, as in prolapsus or elongation of the neck? or high up, as when lifted by pregnancy or morbid growths? Is it tipped forward behind the pubis, as in retroversion of the fundus, or is it back by the sacrum, as in anteversion? Is the cervix larger than normal, as in congestion and inflammation? Is it hard, or is it soft? Is it hot and tender? and does it bleed on the slightest touch? Is the os well closed, or is it patulous? and is there exuding a thick gelatinous secretion? and is there present that soft velvety ring of granulation never to be mistaken by the educated finger, and never recognized by the careless examiner? Is the uterus movable in the pelvis, or is it fixed by cellulitis, the result of cancerous infiltration? and is there present the hard, unyielding border with the crumbly surface, and a tendency to bleed whenever touched? or do we find smooth hard lobes or knobs dotted over the end of the cervix, as in the early stage of cancer? and if so, we must be particular to examine whether the fissures between the elevations are all traceable to the os, for if that is the case, they are probably the result of laceration, and the irregularities are not the result of cancerous deposit. Then, passing the finger up behind the neck of the uterus, the os being in the normal position, do we find a lump there, due either to retroflexion, fibrous tumor, or impacted rectum? and in front is there one due to antelexion, fibrous tumor, or stone in the bladder? Is the condition of the vagina normal? and is there anything to be discovered by pressure of the pelvic areolar tissue in all directions through the wall of the vagina? if not, then we may place the left hand on the abdomen, just above the pubis, and, by bimanual palpation, proceed to examine that part of the uterus out of reach of the finger, within the vagina. I have often been told by students that they found this conjoined manipulation unsatisfactory, and were unable to engage the uterus between the two hands. I am of the opinion that the cause of their failure has been that they endeavored to press the hand on the abdomen down to the uterus, when they should have lifted the uterus up to it with the other hand. With two fingers in the vagina, passed as far as possible up behind the neck of the uterus, you can lift it upwards and forwards, so that in all except very fat women the fundus can be readily felt with the hand on the abdomen, and the entire surface be examined. The posterior wall of the uterus may be examined by introducing the finger high up within the rectum, and at the same time drawing the uterus down with a tenaculum hooked into the posterior lip of the os. We must not expect the uterus to descend at once, but by steady traction we shall cause the supports to relax,

and shall be able to bring it down as far as is requisite. We can examine the recto-vaginal space by introducing the finger into the rectum and the thumb into the vagina. It is often necessary to examine the bladder, and this is by no means a difficult operation. The female urethra is so short and dilatable that I am in the habit constantly of introducing my finger within the bladder for purposes of exploration, and I am somewhat surprised that the condition of the bladder is so seldom investigated in this way by gynecologists when there are so many cases in which it is out of order, and an examination with the finger so often clears up the diagnosis. The patient being etherized, it is only necessary to use the forceps or the uterine dilator to dilate the urethra enough to admit the end of the little finger, which, having first oiled, you introduce, and by rotating and pushing it gently forward for a few moments, it will pass through. Now withdraw it and introduce the tip of the index-finger in the same way until it passes into the bladder. There is, of course, some pain after the patient comes from under the influence of the ether, but this is remedied by an opiate; and the incontinence of urine is soon gone. I have never seen any bad results from the introduction of the finger within the bladder, and I have done it many times. There is not time in one lecture to even allude to all the obscure sexual difficulties that may be cleared up by a digital examination; but if in this hasty review of some of them I have convinced you of its importance as an aid in diagnosis, and you will improve your opportunities in the education and use of it, I shall be satisfied and you will be benefited. If we fail to discover the difficulty by a digital examination and with the use of the speculum, we must then explore the cavity of the uterus; and to aid us in this manipulation we have the uterine sound or probe. The one I prefer, and that I have shown you, is of small size, is made of copper, and is perfectly smooth. There are no marks to indicate the inches, and there is no knob two and a half inches from the end; these are of no use, and if you bend the instrument much, as you will be obliged to, you will find that it will be constantly breaking off at these indentations. When you wish to measure the depth of the uterine cavity, introduce the sound, carry the forceps up to the os and then withdraw the two together. Now, this sound is a very reliable diagnostic instrument, if used in a careful and thoughtful manner; and it is of no use, and is capable of doing great harm, if used carelessly. I should be sorry to have you think the introduction of and the exploration of the uterine cavity with the uterine sound an operation requiring no skill: on the contrary, it often taxes the patience of the most adroit; and I have seen most unfortunate results from its use by the inexperienced. A careful digital examination should always precede the use of the sound, for by it we learn the position of the uterus, and whether we have version or flexion to deal with; and then, and not till then, do we know how to shape the sound or what direction to give it. The instrument should always be oiled, and we may use the specu-

lum or not, but I think you will find the operation much less difficult if you use the bivalve speculum than if you proceed without it. Sometimes the sound passes to the fundus of the uterus without any difficulty, but in many cases after you have passed it something more than an inch up the cervical canal, it meets with an obstruction, and the desire to use force to overcome the difficulty is almost irresistible; but this must not be done. If the sound does not go in, *the point of the instrument is not directed in the axis of the canal*, and you must withdraw it, and give it a different curve. If after repeated efforts you fail to introduce it, you will often succeed if you take the tenaculum and draw down the lower end of the uterus and hold it there while you pass the sound. In this way you straighten the canal, and the difficulty is removed. You will do well to remember what I have said about the sound, for I have been told by very many young physicians that they found difficulty in the use of it; and, as I have said before, cases are not uncommon where injury has been done with it. It is only a short time since I was called to the assistance of a young physician who, failing to recognize the case as one of ante flexion, had pushed the sound directly through the posterior wall of the uterus, and it was only arrested by coming in contact with the sacrum; fortunately, the patient recovered. The examination with the sound gives us information in regard to the depth and direction of the uterine cavity, and also as to the sensitiveness of the mucous membrane, but there are cases in which, both for diagnosis and treatment, it becomes necessary to dilate the canal sufficiently to admit the finger. There are several ways of accomplishing this. The parts may be rapidly dilated with the uterine dilator sufficiently to admit the finger far enough to complete the dilatation, or you may adopt the slower method of dilating with tents of sponge or sea-tangle. To introduce a sponge-tent, hook a tenaculum into the posterior lip of the os, and draw the cervix well down into the speculum, seize the tent with a strong forceps, dip it in oil, and by rotating it at the same time you push it forward, you will be able in most cases to introduce a tent large enough to complete the dilatation, and thereby avoid the necessity for the introduction of the second tent, for it is not a matter of indifference whether you use one tent or more. The reason is that on the removal of the first tent the mucous membrane is seen to be more or less abraded, and in the most favorable condition to absorb putrid discharges retained in contact by subsequent tents. Unfortunate results are so frequent from this cause that I invariably use one tent only, and if further dilatation be required use the finger or the uterine dilator.

TREATMENT OF VENEREAL WARTS AND CONDYLOMATA (*The Canada Medical Record*, July, 1874).—Wm. Bury recently cured two cases of venereal warts which had obstinately resisted treatment by strong nitric acid, sulphate of copper, and the scissors, by applying the acid nitrate of mercury followed by poultices of linseed meal. Two applications sufficed to make a perfect cure.

ORIGINAL COMMUNICATIONS.

A CASE OF MOVABLE EXUDATION IN THE TYMPANIC CAVITY, ATTENDED WITH VARIABLE HEARING.

BY CHARLES H. BURNETT, M.D.,

Aural Surgeon to the Presbyterian Hospital in Philadelphia, and Surgeon-in-charge of the Infirmary for Diseases of the Ear.

THE case about to be related is interesting from the fact that the diagnosis was greatly aided by the subjective symptoms.

Jacob Y., age 55, a large, strong man, a furnace-maker, applied for relief from deafness in the left ear, at the Infirmary for Diseases of the Ear, in June of this year. The patient stated that his right ear was greatly diseased when he was eight years old, and "that a polypus was taken from it, and the ear was then burnt with blue-stone." Since then he has had no hearing in that ear, and inspection reveals total occlusion of the auditory meatus by a diaphragm covered with skin. The skin, forming, as it were, the false or new fundus of the auditory meatus, is not very sensitive, and a paracentesis-needle may be pushed through it several millimetres until the instrument strikes bony tissue. The patient, a very intelligent man, states that when Politzer's or Valsalva's method of inflation is used he feels the air enter each middle ear alike. In this instance, however, he sought relief for an increasing deafness of recent origin in the left,—the heretofore good ear. He could assign no reason for its onset or persistence, as there had been no attack of pain nor any extraordinary event from which to date its occurrence. The drum-membrane presented nothing positively abnormal in its appearance, and as the right drum-membrane was wanting, the relative appearances of the good ear were of no value. The tuning-fork placed on the vertex was heard better in the right—the occluded ear—than in the left ear. External sounds—*i.e.*, sounds conveyed through the air—could not be heard at all in the right ear. The watch was heard $\frac{6 \text{ in.}}{40 \text{ ft.}}$ in the left ear, and the voice about three feet.

Catheterization of the left Eustachian tube forced air into the tympanic cavity, with moist râles, and was followed by considerable improvement in hearing, amounting to $\frac{12 \text{ in.}}{40 \text{ ft.}}$ for the watch, and six feet for the voice. The improvement in hearing persisted for two or three days, and then disappeared, the hearing sinking to six inches for the watch, below which it never fell. This treatment with the catheter was pursued for several weeks, with invariably the same results. There were no signs of faucial or nasal catarrh, and the membrana tympani remained unaltered in appearance. The patient at last stated that he had constantly felt a "drop (of fluid) in his ear," and that when he lay down at night he could hear as well as ever, but when he arose in the morning "the drop came back in his ear and he was deaf." After the narration of these subjective phenomena, the patient was placed in a chair, and told to bend his head alternately backward and forward, and upon doing so his hearing was found to *vary with the positions assumed*. He stated that as he moved his head he would "feel the drop move," and I discovered that he really could hear the watch twice as well in some positions as in others. This variable hearing was at its maximum when the head was thrown backward,—*i.e.*, when the position of the head most closely resembled that assumed when the patient was in a supine position in bed, and the hearing was at a minimum when the head was erect or thrown a little forward,—*i.e.*, in about the position the patient usually carried his head in the pursuit of his daily avocation.

From this examination, together with the statement of the subjective symptoms, I felt convinced that there was a collection of movable fluid within the tympanum, which caused this deafness, and that a paracentesis of the membrana tympani would relieve it. I then made a free incision in the postero-inferior quadrant of the membrana tympani, and a gentle inflation of the tympanum by Valsalva's method forced a large drop of light-yellow serum into the external auditory meatus. The patient instantly expressed great relief, saying that the "drop had gone, and that he could hear distinctly." I then found that the hearing had risen to $\frac{15 \text{ ft.}}{40 \text{ ft.}}$ for the watch, and the voice was heard normally.

The patient was instructed to inflate the tympanum by the method of Valsalva several times during the day, in order to thoroughly empty the tympanic cavity of all fluid. This course was pursued for forty-eight hours, at the expiration of which the perforation healed, and the *hearing remained normal*.

Remarks.—The presence and recognition of movable exudations in the tympanum have been fully described by Politzer several years ago (*Wiener Med. Wochenschr.*, 1867, and *Wiener Med. Presse*, 1869). The symptoms produced by their presence are deafness, altered appearance of the membrana tympani, and, if the membrana tympani is thin, visibility of the fluid contained in the tympanum. In such cases the level of the fluid appears as a dark line on the membrane, but, after catheterization, bubbles of air may take the place of the previously undisturbed fluid.

Cases similar to the one under consideration are thus accounted for by Politzer, *loc. cit.*, 1869, p. 2: "Closure of the Eustachian tube causes a rarefaction of the air in the tympanum. The diminished pressure thus produced upon the vessels of the tympanum, already distended by hyperæmia, permits a ready escape of serous fluid through the walls of the vessels."

In the case just described, deafness more or less relieved by the catheterization of the Eustachian tube, the subjective symptom already described as "the drop," and the variable hearing as revealed by the watch, were the prominent symptoms.

The appearances of the membrana tympani were unaltered excepting a slight retraction, and the fluid contents of the tympanum were, of course, invisible through the drum-membrane.

The deafness in this instance was caused by the impeding influence of the fluid in the tympanic cavity upon the ossicula auditus and the fenestræ of the labyrinth. The temporary relief afforded to the hearing by the catheter was due to the unloading of the chain of bones and the fenestræ, and the resumption of their vibratable functions. "The drop" was the perception by the patient of the motions of the fluid contained in the tympanic cavity, and the variable hearing produced by the positions of the head of the patient was caused by a partial unloading of the conducting apparatus of the ear, as the fluid gravitated under various attitudes assumed by the patient, into portions of the tympanum remote from the ossicles and the fenestræ.

In conclusion, I would draw attention to a phenomenon observed in this case, and in other

cases, of fluid accumulation behind the drum-membrane.

At the moment the knife touched the membrana tympani I failed to perceive the peculiar sound as well as the sensation communicated through the instrument as it touches a tightly-stretched and isolated membrane. This is due to the fact that the membrana tympani was so much encroached upon by the fluid contained in the tympanum that it no longer acted as an isolated membrane. I would therefore add this peculiar doughy or inelastic feeling in the membrana tympani to the diagnostic signs of an accumulation of fluid behind the membrane, and I consider it one of especial benefit in a case like this, where there were none of the peculiar ocular manifestations which usually characterize this condition of the ear.

This fact might be utilized before the operation by gently percussing the membrana tympani with a delicate blunt probe, which would elicit the peculiar acoustic effect of an isolated membrane if the membrana tympani were unimpeded; or if the membrana tympani had ceased to act as an isolated membrane, the proposed percussion would reveal the fact by the doughy sensation or dull sound produced by the properly manipulated probe.

127 SOUTH EIGHTEENTH STREET.

NOTES OF HOSPITAL PRACTICE.

UNIVERSITY OF PENNSYLVANIA.

CLINIC OF DR. J. E. GARRETSON.

DIAGNOSIS OF A TUMOR.

GENTLEMEN,—I have taken occasion very frequently to say to you that to diagnose the character of a tumor for purposes of treatment does not seem at all a difficult matter, for the reason that there are, clinically speaking, but two kinds of tumors, and any morbid enlargement with which we meet will be found to belong to the one or other of these classes.

A tumor has in itself the explanation of its existence; or otherwise it is without such self-explanation. A tumor belonging to the first class contains its own history, and suggests of itself the character of treatment demanded. A tumor belonging to the second class tells nothing, and leaves us to our own inferences.

Tumors of the first class are, in themselves, necessarily benign.

Tumors of the second class are found almost certainly to prove cancerous.*

Benign tumors are of multitudinous signification. Examples: ranula, hernia, wens, etc.

Cancerous tumors, however they may differ in expression, are of a common meaning. There is but one cancer, and we may agree with the English school of pathology in viewing it as a disease of constitutional signification, and not with Virchow, Woodward, and their adherents, who esteem it as being primarily of local origin.

The self-explaining tumors demand for their recognition the possession of anatomical and physiological knowledge sufficient for the reading of their riddles. For example, he who discovers in a tumor of the groin an undescended testicle must know of the meaning of

the inguinal canal; he who diagnoses a sebaceous cyst is to read the perversion in a knowledge of the oil-secreting glands; he who recognizes a ranula must have understanding of the salivary outlets. Knowing of all the associations of a part in which a tumor appears, he is to find the meaning of the tumor—if it has local meaning—in the *something* which is seen to be wrong.

Let us suppose, however, that we meet with a tumor in a part,—in any part,—and that we find ourselves unable to explain its presence in any derangement of the part. What is to be the conclusion? We are to infer either that we are ignorant concerning the relations, or else, being satisfied that we know properly and fully the locality, that the tumor is not one of local, but of systemic meaning. It would be for us, then, if satisfied of the latter conclusion, to consider tumors of constitutional expression. And here, through exclusion, we would very quickly be able to determine whether or not we had to deal with scrofulosis, the venereal disease, or with *that something* of which we know so little,—the cancer-vice.

As an example of each manner in diagnosis, I now bring before you five patients, every one of whom has a tumor occupying the same locality, and all being of a common appearance.

[The cut is taken from a photograph of one of the five, who died, a few months subsequently, from cancer.—Case V.]

Case I.—The history of this case exhibits it as one of acute signification. The trouble commenced, as the patient tells us, in an aching tooth. Opening the mouth, we remark at once a lower molar evidently raised in its socket, and about which there is much inflammation. This, as the *something wrong*, we see, and we see nothing else in the way of a cause. Without enlarging on the subject, I may say that, let the tumor prove what it will, the most sensible thing to be done is either to remove the tooth we find diseased, or otherwise treat it. This we are to do because we know the tumor to be an enlargement of the submaxillary gland, and, finding no other cause for such enlargement than the one just discovered, we may not possibly do anything better than so direct our treatment. This tumor, I hold, explains itself as a sympathetic enlargement of the salivary gland. The cure of the enlargement will be found in the cure of that which irritates the region. We will extract the tooth.

Case II.—Here we have a second tumor in the submaxillary region; differing, however, from the first, in being less circumscribed. The history of this case expresses it also as of acute signification, although it certainly would not be necessary to learn this of the patient, remarking the characteristic features of all the expressions. The parts are very red and very hot; they may only be very painful.

Attempting to open the mouth of this patient, we discover that she has a broken lower jaw,—and this accident has resulted from the stroke of a brick. We will cure this tumor by curing the broken bone,—by putting the parts in a splint and thus securing rest, and by employing such local antiphlogistic means as may prove to be required. Certainly this tumor explains itself.

Case III.—In an examination of this case, I expose to you caries of the jaw; and if for a single moment you glance at the decaying and otherwise diseased

* A single exception to the placing of tumors into two classes exists in the case of hydatid growths.

mass of overlying teeth, you will be at no loss to account for the trouble of the bone. This is another instance in which the tumor originates in sympathy with a local disturbance, and explains itself. Our treatment here will be, first, to remove the teeth; second, to scrape away the dead and dying portion of the maxilla. The cure of the caries will prove the cure of the morbid enlargement. Or, having operated on the bone, we will, not unlikely, find advantage in applying to the face of the tumor a mixture of equal parts of tincture of iodine and olive oil. Alluding to this combination, I might direct your attention, in passing, to its efficacy in all cases of subacute or chronic inflammations; I have come to depend on it as a kind of specific.

Case IV.—The tumor we here find secondary to necrosis of the jaw, and the necrosis has its origin in conditions of strictly local signification. Any one of you can here explain the cause of the enlargement, and judge as to what is to be done to effect a cure. We must wait for a complete exfoliation of the sequestrum, and then remove it. The tumor will take care of itself.

Case V.—Here is a fifth tumor, having a common appearance with the others; palpation, however, discovers a difference. This tumor seems to the touch to be more or less lobulated; it is also very hard. It is without pain on pressure, but has occasional sharp, sting-like sensations running through it.

Not unnecessarily to detain you, I would say that before bringing this patient into the room, I made a thorough examination of the case with a view to finding a cause for the tumor, but the search resulted in nothing: that is to say, this young man has no bad teeth; no lesion from accident; no caries; no necrosis; no local anything that explains his condition. In a search continued in the constitutional direction, I have succeeded no better. There is no scrofulosis; no tuberculosis; no venereal disease; no anything familiar to us, that directs how to act in the case. Now, because the tumor is independent of common causes of irritation, I know of no better practice than to view it as an expression of cancer, and so direct our practice. In other words, let the enlargement alone, and wait developments; for if it should prove that the disease is cancer, having no specific for such a vice, we find ourselves powerless; certainly the knife could not be used on the tumor before us, as it is without distinctness of boundary, and to meddle with true cancer so situated with sorbefacient and other preparations is to do nothing but harm. If, on the contrary, this tumor should not prove to be cancerous, we certainly act with greatest show of wisdom in doing nothing until we find out what is to be done—*secundum artem*.

I take it upon my experience, however, to say that in three months I will exhibit this particular case again before you, in the condition of fungus hæmatodes. I take it upon myself to declare the tumor cancerous, on the simple ground that it declares itself to be nothing different.

UNIVERSITY HOSPITAL.

SURGICAL CLINIC OF PROF. AGNEW, SEPT. 16, 1874.

TWO CASES OF HYDROCELE.

TWO cases of hydrocele were presented,—one in a boy 2½ years of age, the other in a man of 30 years. In both, the complaint had existed for several months; occupying in the child the right side, and in the adult the left side of the scrotum. Prof. Agnew said that the tumor for which hydrocele in a child is most liable to be mistaken is hernia, but there are several points of difference which render the diagnosis not difficult. If we study the characteristics of a hydrocele

we find it to be an oval or pyriform tumor, uniform in outline, translucent by transmitted light, permanent, and giving to the touch a characteristic elastic feel. Hernia is apt to be more or less irregular in outline, but may present very much the shape of a hydrocele; it is not translucent, though the hernial sac may contain sufficient serous fluid to render a portion of the tumor pervious to light. It is not a constant tumor, but, unless strangulated (in which case there are symptoms which give unmistakable evidence of the condition), disappears when the patient assumes a recumbent posture, or may be easily reduced by proper manipulation. The fingers placed upon a hernial tumor feel an impulse from the acts of coughing, crying, etc. Besides, a hernia first appears at the abdominal ring, or in the canal, and grows downward, while in hydrocele of the tunica vaginalis testis the swelling begins below and extends upwards. In the adult there are other tumors from which we are obliged to diagnose hydrocele: enlarged testicle, tubercular, cystic, and cancerous diseases of the gland. One characteristic of all these is their increased weight as compared with hydrocele; another is the entire absence of translucency. The very rapid growth of malignant sarcocele is an important diagnostic sign. The treatment of hydrocele is of two kinds: palliative and curative. The former consists in evacuating the tumor by puncture with trocar and canula; the curative treatment varies with the age of the patient. In children of the age of the youngest of these patients, or younger, the fluid will sometimes be absorbed under the influence of external applications of a solution of muriate of ammonia or of tincture of iodine; but a more satisfactory method is the introduction of a thread through the walls of the sac. In the adult the most satisfactory method is the puncture of the sac, evacuation of its contents, and the injection of tincture of iodine. The first patient was etherized, and a silk thread introduced through the walls of the tumor, the ends being tied loosely together; the contents of the sac were then allowed to escape. Prof. Agnew directed that the thread be removed in twenty-four hours, by which time sufficient irritation would be excited to effect a cure. The other case was first tapped, and the fluid drawn off in the usual manner. A little more than fʒij of tincture of iodine was then injected, and allowed to remain.

Prof. Agnew said that it was essential to a favorable result to retain the iodine in the cavity of the sac, and its withdrawal by some operators he considered the cause of failure with them in the use of this agent; that he believed if the operation be performed as directed, and a sufficient quantity injected (fʒij to fʒijss), a cure would be effected in all cases unless the hydrocele be of extraordinary size. The patient was directed to return immediately to his home and go to bed. The lecturer said that active inflammatory symptoms would soon manifest themselves, and the part would swell greatly, and require careful support. Five or six days after the operation the patient may usually be allowed to rise from bed, being careful to continue the support of the scrotum by a suspensory bandage. Should the inflammation excited by the operation be too violent,—a very rare occurrence,—local applications of lead-water and laudanum may be required. In the course of a few weeks the swelling will have completely subsided and a cure be effected. Prof. Agnew spoke of the necessity of a careful examination after drawing off the fluid of hydrocele, to ascertain that it be not complicated by hernia or organic disease of the testicle, which last condition contra-indicates the use of iodine injections.

COLLE'S FRACTURE OF RADIUS.

The next patient was a woman 37 years of age, with a fracture of the lower end of the left radius of the kind

usually known as Colle's fracture. This was the result of a fall upon the extended hand, occurring four days ago. Prof. Agnew described the three kinds of fracture of the lower end of the radius, to which the names of Barton, Colle, and Smith are given respectively. The first is a rare form, and only includes fractures extending into the wrist-joint. Barton described two forms of this fracture: one in which the fracture extended from the palmar to the dorsal surface of the bone, and obliquely from without downward and inwards, separating the styloid process of the radius; the other extending from the outer to the inner side, and from the dorsal surface obliquely downwards into the joint, detaching the dorsal border of the articulating extremity.

The name of Colle's fracture is given to any fracture of the radius below a point two and a half inches from its extremity, which does not enter the joint. Smith's fracture occurs at a distance of at least two and a half inches from the end of the radius. The treatment of all these different forms is essentially the same, being directed to the reduction of a deformity which consists in the displacement of the lower fragment and hand backward and to the radial side. This deformity is more marked usually in those fractures occurring very near the extremity of the bone; particularly if the fracture be oblique and complicated by dislocation of the lower end of the ulna, in which case the styloid process of this bone projects conspicuously.

Prof. Agnew said he considered the best method of treating these fractures was by Bond's splint, the shape of which abducts the hand strongly to the ulnar side. The hand grasping the block at the extremity of the splint admits of motion of the fingers, which Prof. A. considers of great importance in preserving the usefulness of the hand. At the same time the antero-posterior deformity is corrected by the use of wedge-shaped pads, one of which is placed upon the dorsal surface over the lower fragment with the base upward, the other on the palmar surface with the base corresponding with the line of fracture looking downward. This had been the treatment in this case, and was continued.

The lecturer called attention to a discoloration highly characteristic of fracture, which is due to hemorrhage from the fractured surfaces, and which does not make its appearance externally for several days after receipt of injury. This is to be distinguished from discoloration due to rupture of more superficial vessels.

TRANSLATIONS.

TRAUMATIC NEURALGIA.—At the recent meeting of the French Association for the Advancement of Science, reported in the *Gazette Hebdomadaire*, September 11, M. Verneuil called attention to a complication of traumatic lesions which, without being very grave, is yet painful, and capable of retarding the work of reparation. It consists in painful sensations, more or less acutely perceived in the wounded locality, in its neighborhood, or even at a considerable distance, supervening during the first few days subsequent to the accident.

These sensations affect a neuralgic character and intermittent type, are not to be explained by ordinary causes of traumatic suffering, resist the ordinary antiphlogistics and narcotics, and yield without difficulty to sulphate of quinine.

M. Verneuil gives this complication the name of *traumatic secondary precocious neuralgia*. Pain is essentially the predominant symptom; its onset is generally sudden, and, once established, it may be continuous or

remittent, or more frequently intermittent, with daily attacks.

Concurrently, contractions or a certain degree of powerlessness of the muscles may be observed. This condition is generally limited to the parts near the wound. Vascular troubles may also exist, strictly due, to all appearance, to the existence of the local pains, and these may even provoke secondary hemorrhages. The wound passes through various modifications. Sometimes it preserves its normal appearance; sometimes it presents a diphtheroid aspect; sometimes even it may become the seat of a true phlegmonous inflammation. These various conditions are only effects of the neuralgia, since they yield very rapidly to sulphate of quinine.

What is the cause of this neuralgia? Is it neuritis, modification of the nervous conductors, etc.? The details of various observations, says M. Verneuil, do not point to the possibility of a pathological cause of this kind; but if the explanation of this neuralgia is not found in traumatism, its seat or its varieties, it may be recognized as having an intimate relation to anterior diathetic conditions or to the previous health of the individual.

These various facts permit the establishment of a diagnosis without difficulty, and allow also of the opportune application of the treatment, which is administration of quinine in proper doses, at regular intervals, and for a sufficient time.

A. V. H.

LIGATION OF THE INTEROSSEOUS ARTERIES OF THE FORE-ARM (*Acad. de Méd.*, September 15).—M. Gosselin read for the author, Prof. Michel, of Nancy, the following communication: In a patient who had received a gunshot wound, producing fracture of the superior extremity of the radius, such profuse hemorrhage supervened that M. Michel was obliged to ligate successively the brachial, in the lower fourth, the radial, the ulnar arteries, in the upper third, and, finally, the trunk of the interosseous. It was not until after the ligation of the latter, now performed for the first time, and heretofore avoided by operators on account of its difficulties, that the hemorrhage was completely arrested.

The following was the operative procedure adopted by M. Michel:

The direction of the muscular interstice of the anterior ulnar and of the flexor sublimis digitorum was traced, and a line drawn from the internal side of the pisiform bone to the epitrochlea as if for the ligation of the ulnar in its superior third.

On this line a cutaneous incision was made three inches at least in length, of which the centre corresponded to the bicipital tuberosity of the radius. The muscular interstice was then divided almost to its superior extremity. Then, flexing the wrist on the fore-arm and the fingers on the hand so as to entirely separate and divide the superficial from the deep flexor above, the origin of the ulnar could be perceived.

Following its posterior aspect, the origin of the trunk of the interosseous could be plainly perceived, enveloped by its accompanying veins. These surroundings rendered the isolation of the vessel a somewhat delicate matter, but one which was surmounted by the exercise of patience. This process by practice becomes easy, and in a short time may become familiar even to students.

The author terminates by the following conclusions:

1. The trunk of the interosseous may become the origin of severe traumatic hemorrhages of the fore-arm and hand.

2. There is every reason, therefore, why the ligation of this artery should be among the procedures of operative surgery.—*Gaz. Méd. de Paris*, September 19, 1874.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, OCTOBER 17, 1874.

EDITORIAL.

TRANSACTIONS OF THE MEDICAL SOCIETY OF THE STATE OF PENNSYLVANIA.

FOR reasons which have been adduced in previous editorials of this journal, it is a matter of grave doubt whether the American Medical Association ever can assume a paramount importance to the profession at large, or ever approximate in this country to the influence wielded by the British Medical Association in Great Britain. These reasons, however, do not apply to the State Medical Societies. Citizens of one commonwealth,—governed, therefore, by the one law and domineered by the same customs,—inhabitants of a territorial district not too large to forbid free intercourse, the members of a State society are in a position to be readily fused into that unity which can alone give strength to a medical association. Believing, as we are inclined to, that the hope of the profession for the future, nay, rather, the very existence of the profession as a profession, lies in the State societies, it is with the greatest of interest that we have examined the Transactions before us. The result is eminently satisfactory. In the brief space of an editorial we can only comment upon a few points which have especially attracted our attention, and must omit notice of much that is worthy of praise. An objection to the eloquent address of the President may be made by some that it is too theological; but since

it has become the fashion for scientists to prolong their vision across the invisible, and mistake for wisdom their own illogical reasonings, it is well, occasionally, to hear a little orthodoxy.

The address on obstetrics is a very elaborate, well-written résumé of recent literature, and must be of especially great value to those who have not access to the libraries of large cities. The address on surgery is really an article on tracheotomy, and we leave the judgment of its value to our surgical friends.

The *pièce de résistance* of the volume is a very learned, laborious article on croup in its relations to tracheotomy, by Dr. Cohen, of this city. It is a paper that should be studied by every man who expects to attempt such operation or to decide as to the propriety of its performance.

The reports of the county medical societies are all of them interesting; containing, it is true, many matters concerning local epidemics as well as medical geology and geography scarcely of general interest, but containing also reports of strange and instructive cases, many good suggestions in therapeutics, and other matters worthy of general attention. We confess that we have been somewhat surprised at the literary ability displayed in most of them, and sincerely wish some of our city contributors would take lessons in English of their authors. We would especially cite, as suggestive, Dr. Corson's remarks on the treatment of pneumonia, and, as remarkable, a case reported by Dr. Randenbush, in which the patient recovered although he had been run through the chest with a scythe, which he had pulled out with his own hands. "The curvature of the scythe cut from the point of entrance obliquely downwards and to the right, severing the cartilage of the third rib on the left side, the sternum and cartilage of the fourth rib on the right side, making a wound in the chest anteriorly six inches in length. The posterior or wound of exit was about two inches long, or the width of the scythe."

Dr. P. R. Palm, of Allentown, states that the root of the *Asarum Canadense* is used in his neighborhood for the production of abortion, and details a case. We had supposed our "wild ginger" was as harmless as peppermint, but certainly the evidence brought forward is remarkable and staggering.

During the year the Society has lost by death the member by whose act it was called into being. It was Dr. Wilmer Worthington who offered, at a meeting of the Chester County Medical Society, in 1847, the preamble and resolutions which led to the organization of the State Society, and to him, there-

fore, the profession of the State owes a debt of gratitude, enhanced by a singularly useful and unselfish public life of many years.

Dr. Worthington was an enthusiastic advocate of everything calculated to elevate the general tone of the profession; doing all that lay in his power by word and by deed. As he has laid the foundations, so we hope others will build; organizing and consolidating the State Society until it becomes a body whose word is paramount in its district, and until it is able to use its influence with success in enforcing upon candidates for professional honors that higher general culture, and more extended and thorough technical education, for which Dr. Worthington so earnestly pleaded.

Any one in doubt as to how much or how little scientific capital is required to fit up a showy *Tribune* bulk-window should read the replies to Dr. Hammond's defence in the last issue of the *New York Medical Journal*. The *London Medical Record* characterizes Dr. Hammond's proposed treatment as "utterly ridiculous." The *Boston Medical and Surgical Journal* speaks of his "having brilliantly closed the hydrophobia season." Some of the Western press have been very outspoken and severe: indeed, we believe the general expression of opinion has been such that it will have a salutary effect in restraining the spread of the newspaper epidemic.

The English colliers appear to appreciate the importance of sanitation. It is stated that eight hundred men at the Windon Collieries in Durham have suffered for a long time from improper water-supply, and have made many complaints to their employers. The latter refusing to listen to these representations, the men have struck. The Durham Pit Villages are said to be an abomination upon the face of the earth, and we hope the laborers will be successful in forcing their employers to give them suitable dwellings.

The "quiz" advertisement to which we alluded in a recent editorial was printed in a column of the paper allotted to advertisements, and in the type and dress of an advertisement. Our judgment was therefore, from the premises, seemingly an inevitable one. Outside evidence has, however, since been brought to our knowledge, showing that the matter was put in the paper by an over-zealous reporter, without the knowledge of the quiz organization.

The famous London surgeon, J. Erich Erichsen, has recently been on a visit to this city, and was the recipient of a complimentary dinner from a number

of medical gentlemen, including most of the prominent medical teachers and authors of our commonwealth. The affair was an exceedingly happy one in all particulars.

Dr. A. J. EIDSON (*The Amer. Med. Journal*, Oct. 1874,—Eclectic) has discovered that labor is greatly facilitated by placing the head of the woman towards the north. Difficult cases should be sent to the magnetic pole.

THE *London Lancet* says, "A contemporary states that a fee of \$150,000 was lately paid to an American surgeon for removing a wen by means of the galvanocautery."

Who was the fortunate man? We suspect the "contemporary" must have been Mark Twain's organ.

CORRESPONDENCE.

NEW YORK SOCIETIES.

NEW YORK, October 6, 1874.

INSANITY OF INEBRIETY.

THE New York Neurological Society held a regular stated monthly meeting last evening, at which two very interesting papers were read: one by Dr. George Burr, of Binghamton, New York, on the Insanity of Inebriety, and the other by James J. O'Dea, of Clifton, Staten Island, New York, entitled, The Philosophy of Suicide.

Dr. Burr remarked substantially as follows:

It has been said many times, when an individual has been seen to sacrifice all consideration and prospect in life for the gratification of a desire for ardent spirits, that such a man must be crazy; that no sane man or woman would thus throw themselves away, and bring ruin upon every hope of the future. This view of the question is but a natural common-sense view; and yet it is held by comparatively few. The most common sentiment is that drunkenness is a vice,—a voluntary act of the subject,—for which he is morally and in every other way responsible. The object of the paper was to trace the relation of most of the forms of inebriety to an impulse as completely morbid as is to be witnessed in well-recognized varieties of impulsive mental derangement. By the term inebriety is meant a condition of the system calling for and demanding, through its sentient apparatus, the immoderate use of alcoholic drinks, either daily or at stated periods, according to the peculiarities of the case. The term does not mean merely a state of intoxication. Neither does it imply any particular effect of alcohol in any form upon the various organs and tissues of the body, nor that condition of the organization which Marcet has so well described as chronic alcoholism. All these are the effects, the consequences, of the indulgence. Other terms are frequently employed to designate this condition, such as methomania, dipsomania, propensity,

thirst. But the term dipsomania—meaning crazy for drink—is the most expressive.

There exists among all nations an inherent desire for ardent stimulants; and this propensity may be divided into two varieties,—1, a normal, healthy desire for stimulants to a moderate extent; 2, an augmented and inordinate demand, entirely at variance with a sound and healthful condition of the body or with its legitimate demands, and impelling the subject of it to acts of debasement and drunkenness.

In 1833, Dr. Woodward, of the Worcester (Massachusetts) Insane Hospital, in a series of essays, maintained that intemperance was a disease, and declared, from his own experience in the management of many hundreds of intemperate persons who had committed crimes which rendered confinement necessary, or who were insane in consequence of this habit, that this disease was amenable to treatment, and that "a large proportion of the intemperate in a well-conducted institution would be radically cured, and would again go into society with health re-established, diseased appetite removed, with principles of temperance well grounded and thoroughly understood, so that they would be afterwards safe and sober men." It must be here remarked that opinions like this have reference only to extreme forms of inebriety; the milder forms have usually been considered to be wicked or vicious indulgences censurable in the highest degree. The speaker differed from these views. He would refer every case of well-marked departure from a normal desire in the use of ardent spirits to the presence of some morbid influence. The difference between the severer and the milder forms of inebriety is one of degree only; the essential nature of each and their pathognomonic symptoms are the same.

The seat of this disease is undoubtedly in the sentient apparatus. It is, however, not to be referred to any particular pair of nerve-trunks, either to the pneumogastric, the glosso-pharyngeal, or the gustatory branch of the fifth pair; but, like the sense of hunger and thirst, or that of the *besoin de respirer*, it prevails throughout the entire organism. It is a morbid perversion of the natural sense. The impressions made upon the sensorium are false and unreal; unnatural wants are created by disordered nerve-communication, and unnatural sensations are experienced. In this respect these sensations somewhat resemble the hallucinations of sight and sound, when, as is well known, false impressions are made upon the eye and ear, and persons see unreal sights and hear unreal sounds.

The insanity of inebriety consists in the almost absolute power exercised by the morbid appetite over the operations of the mind, exciting ideas, emotions, and passions entirely at variance with the natural characteristics of the individual. The milder types consist of an abandonment of the individual to the influence of alcohol. He is impelled to commit acts which his sound and sober judgment would condemn. He does not have liberty of action, but must obey the strong uncompromising impulse which pervades his entire organism. He must drink, notwithstanding poverty is

coming in at the door, and starvation is staring his family in the face, and his character and reputation are passing away "like a summer cloud;" nevertheless he must drink! The parallel between the morbid impulse to drink and other and well-recognized branches of morbid impulse, as well as other forms of mental disorders, is very striking; and the exciting causes will be found to be identical. It may be safely asserted that the ratio of insane to the population of the United States is probably greater than in any other nation; and this for very good reasons. The wear and tear of life is more severe here than elsewhere: the great desire to accumulate wealth, the rage for speculation, the constant recurrence of political campaigns, and a certain amount of religious fanaticism, are causes that are constantly operating to disturb and exhaust mental energy. No time is given to recuperate wasted energies. What wonder, then, that many fall out, and the faculties become deranged! These same causes operate to excite inebriety, only, it is believed, in a much larger ratio. Compared with the number of insane, the number of inebriates must be tenfold. These causes augment and intensify the desire for stimulants. Alcoholic and kindred drinks are immediately resorted to, and the diseased appetite is immediately inaugurated.

Among the special causes of intemperance, which, in one case, induces disordered sentiments or feelings, in another, a disordered mind, and in another, a disordered appetite, are a blow upon the head, and concussion of the brain from a fall. In one, the injury has been succeeded by a mania proper; in a second, a complete transformation of character; while in a third is developed a love for ardent spirits. Other causes are, inheritance, irritation, suggestion; and in no variety of morbid impulse does *habit* have a more potent effect.

In conclusion, he reiterated his theory that the habit of drinking is caused by a disordered state of the mind. To refer the self-destructive acts of the inebriate to the same influences which in others incite to kill, to commit suicide, to steal, or to burn, appears to him to be consistent and proper. Whatever gentlemen may think, all will no doubt concur in the propriety of studying the subject from this stand-point, in the earnest hope that eventually some remedy will be found, some check be placed upon the sad and fearful ravages of inebriety. In relation to inebriate asylums, the essayist is a firm believer in the utility of public institutions for the exclusive treatment of inebriates. In this he was aware that he differed from the learned President of this Society (Dr. Hammond), whose late comments upon the management of inebriate asylums he regards as too sweeping and denunciatory. He admitted the justness of the learned gentleman's criticism, to a certain extent, upon the present management of the institutions now in operation. The means of restraint employed are, perhaps, not adequate; but it will be found that one of the most difficult problems to solve ever attempted is the proper adjustment, discipline, care, and treatment of inebriates. Many of the regulations must be sub-

mitted to voluntarily, and the patient himself must earnestly co-operate in every measure calculated to promote his reformation. He must not only concur, but he must co-operate in all such measures. In the New York State Inebriate Asylum, at Binghamton, from the 1st of September, 1873, to the 1st of September, 1874, the number of patients admitted was 190. Of these 23, or 13 $\frac{1}{3}$ per cent., have proved refractory and unsubmitive. The rest have quietly submitted to the rules and discipline of the institution; and many have gone out, as is believed, fully restored. Measures are now being taken to inquire into the subsequent history of all those who have been inmates of the institution. A small proportion relapse. Of the 190 inmates during 1873-4, 1 has returned three times, and 16 are there for the second term of treatment. But there is a propensity to return in many diseases, especially when the person is exposed to the exciting causes. Mental disorders, as is well known, are very liable to return; and the records of the lunatic asylums will probably show quite as many relapses in proportion as will the inebriate institutions.

THE PHILOSOPHY OF SUICIDE.

By the term suicide we are to understand the intentional destruction of one's own life. It embraces all who kill themselves intentionally, or, as the legal phrase expresses it, "with malice aforethought," whatever be the cause of the act or the mental condition of the agent. It excludes those whose death results from immoderate self-indulgence or the too ardent pursuit of a favorite scheme. Fundamentally, suicide has reference to the individual in his personal and relational life. Its causes are of three main orders: general, special, and personal. The general order of causes exists everywhere and under all circumstances, and includes religious belief, philosophy, age, and sex. The special order is that which is more circumscribed in range. It comprises all the various circumstances and accidents growing out of the social relations of the individual,—love-troubles, domestic difficulties, legal entanglements, habits of intemperance and immorality, financial losses and embarrassments. The personal order of causes has reference chiefly to the bodily and mental health of the individual.

It would be impossible in these short notes to do justice to the paper of Dr. O'Dea, which he intends to continue from time to time, treating the subject thoroughly. The following table, however, of suicides of ancient Greeks and Romans, together with a few remarks on the influence of sex and age on suicides, may be of interest:

NAME.	MODE.	CAUSE.
Pythagoras	Starvation	Tædium vitæ.
Demosthenes	Starvation	Downfall of Athens.
Clitomachus	?	Tædium vitæ.
Stilpo	Intoxication	?
Metrocles	Suffocation	Old age.
Menippus	Hanging	Financial losses.
Demonax	Starvation	Loss of influence consequent on old age.
Zeno	Strangulation	Fracture of a finger.
Seneca	Phlebotomy	Political reasons.

NAME.	MODE.	CAUSE.
Pauline, wife of Seneca	Phlebotomy	An attempt caused by unwillingness to survive her husband.
Cato	Wound	Political reasons.
Otho	Wound	Political reasons.
Panthea	Poison	Grief at the loss of her husband in battle.
Phila	Poison	Defeat and flight of her husband.
Arria	Wound	Defeat and arrest of her husband.
Scipio	Wound	Because he had fallen into the hands of his enemies.
Socrates	Starvation	The victory of Philip at Chæroneæ.
C. Lutatius	Suffocation	To avoid falling into the hands of Marius.
Lollus	Wound	The ill-will of Caius Cæsar.
Nero	Wound	Because condemned to death by the Roman Senate and people.
Lycambus	Hanging	Ridicule.
Lambianus	Self-interment	Because his writings were condemned and burned.
Aristarchus	?	A dropsy.
Erasistratus	Poison	An ulcer.
Eratosthenes	?	Loss of sight.
Silvius Italicus	Starvation	An incurable disease.
Diogenes	?	A violent fever.
Porcia	Swallowed live coals	Domestic affliction.

The influence of age upon suicide is a study of more than speculative interest, on account of its practical bearings and of the ease and precision with which it can be demonstrated. By age is meant the critical periods of life. These periods having many components besides the mere fact of years, it is apparent that what we have to examine is a many-sided phenomenon, including together with it the advance in life, the workings of physiological, mental, and sociological causes.

The maximum of suicides for both sexes occurs between the ages of 25 and 55. Previous to the twenty-fifth year there is a sudden increase from two suicides between the ages of 5 and 10 to one hundred and thirty-six between 20 and 25. After 55 the tendency to suicide declines, but more gradually than it rose, except at 65, where the number increases from eighty-one to eighty-three,—a rise so slight, however, as to be little worth considering.

There are, therefore, three suicidal periods in life: those of organic and mental growth, of organic and mental completion, and of organic and mental decline. In the first the chart shows 80; in the second, 942; and in the third, 311. Comparing the periods in round numbers, it may be said that they are as one for childhood and adolescence to twelve for adult life and to four for the years of bodily and mental decay.

The influence of sex and its attending circumstances upon suicide at the different periods of life is shown upon the charts. With females, as among males, there is a sudden and abrupt rise until the twenty-fifth year is reached. This rise is continued to the thirty-fifth year, at which the maximum of suicides occurs among women. The period from the twenty-fifth to the thirty-fifth year corresponds to that of the greatest pressure from domestic troubles and responsibilities, and also with the greatest activity of the maternal functions. The line thence descends abruptly to the forty-fifth year, whence it rises to the fiftieth—the critical period of mature female life,—and then goes down, down, until it reaches the level from which it started.

There are, therefore, two culminating points, and whilst the line on the male chart is undulating and sustained, that on the female chart is vertical and abrupt. The lower of the male culminating points is the higher of the female, and, contrariwise, the lower of the female is the higher of the male.

These charts do not show the relative frequency of suicides among the two sexes. The ratio of suicides to population in the United States is (for the period covered by the last decennial census) 25 to 100,000 among males, and 3 to 100,000 among females. The only periods at which suicides are nearly equal for both sexes is from 15 to 20 years, during which the number of boy-suicides was 34, of girl-suicides 32. After this the number of suicides among males is much greater than among females.

W.

SELECTIONS.

PREVENTION AND TREATMENT OF PUERPERAL DISEASES.

[We have extracted the following paper from the American Supplement to the *Obstetrical Journal of Great Britain and Ireland*, because it seems to us worthy of being read by the general profession, as embodying views and actions exceedingly novel and successful on a most important practical subject.]

THE Preston Retreat is a small lying-in hospital for reputable married women. The yearly average has thus far been about one hundred labors, but it is now rapidly increasing. It contains four wards, each with a capacity of 9153 cubic feet, and each furnished with five beds, of which not more than four are generally occupied at one time. The ventilation in winter is obtained by the escape of the cold and foul air through an old-fashioned fireplace, in which a jet of gas is kept constantly burning, and by the free admission of pure air, which has been heated in the basement by passing around steam-chests, with large radiating surfaces. In summer, the admission of pure air depends exclusively upon open doors and windows, and the ventilation is, consequently, less perfect than in winter. In the spring and autumn months, there are many days in which the temperature is too warm for the free admission of heated air, and yet too cold for open windows. These are, therefore, the two seasons of the year which I dread the most, and in which I avoid, as much as possible, crowding the wards.

The wards are used invariably in rotation. By close management, and by crowding walking patients together, one of these wards in its turn stands idle for two or three weeks. During this time the doors and windows are kept open. Before it is again occupied by patients, the walls, floor, wood-work, and furniture—all of which are painted—are thoroughly scrubbed with carbolic acid soap, and then mopped over with a solution of half a pint of carbolic acid (Calvert's No. 4), to one pail of water. From this time until the ward is again vacated, no portion of it, not even the floor, unless accidentally soiled, is touched with water.

The nurses wear such clothing only as can be washed. As soon as the inmates of a ward are well enough to take care of themselves or of one another, their nurse is relieved from duty. She now takes a soap bath, puts on an entirely clean suit of clothes, and goes into a ward which has been thoroughly ventilated and cleansed.

Before a new batch of patients falls to her care, she has had one week or more of rest. I visit the wards thrice daily, beginning always with the ward last occupied, and with the patient last delivered. Whenever a vaginal examination is needed, it is put off until all the other patients have been seen. The examining finger is then anointed with an ointment containing carbolic acid, and the hands are afterwards washed with carbolic acid soap. Post-mortem examinations I never perform. Whenever one is needed, an expert is called in, and remunerated for his services.

The beds consist of a tick filled with fresh straw and covered with an army blanket. After the discharge of a patient, her bed is emptied, and the tick, blanket, and bedclothes are boiled in water to which a little carbolic acid has been added. Each bed is furnished with a feather bolster and pillow, which are exposed on slats to the air when not in use. Once a year every bolster and pillow-tick in the house is washed, and the feathers baked and "renovated," as it is technically termed. They also pass through the same process whenever soiled, or whenever used by a patient whose convalescence has been delayed.

The patients come chiefly from the poorest classes; but many in more comfortable circumstances, with the hope of getting better care, seek admission on account of some difficulty attending their former labors. On this account, the proportion of difficult labors is much above the average. Those patients who have families often put off coming in until labor has actually begun, and then leave at the earliest possible moment. Notwithstanding this, since patients have the privilege of remaining four weeks after their delivery, the average stay of each one is sixteen days before delivery, and eighteen days after. Every patient, upon admission, takes a warm bath, and at least one a week thereafter before her delivery. If she exhibits signs of feeble health, she is at once put upon the use of quinia, and of the house mixture, consisting of two parts of the muriated tincture of iron, with three of dilute phosphoric acid. The habitual constipation of pregnancy is met by the administration, either in the morning of a teaspoonful of pulv. glycyrrhizæ comp. of the Prussian Pharmacopœia; or, at bedtime, of four Lady Webster's pills (pil. stomachicæ). When a more active purge is needed, the pulv. jalapæ comp. or the pil. cathartic. comp. (U. S. P.) is given. Headache and sleeplessness are treated by warm baths, by full doses of potassic bromide, and by the above-named medicines, when indicated; albuminuria is dealt with in pretty much the same way, but always with iron and phosphoric acid. The regular diet is plain and wholesome, yet more liberal than is usual in charitable institutions. Apart from the frequent use of aperients, a relaxed condition of the bowels is promoted by serving table-syrups at every meal, by fruits—fresh or dried, according to the season—and by all such vegetables as can be eaten raw, viz., lettuce, cress, radishes, leeks, onions, tomatoes, cucumbers, and cabbages. Of these, in this latitude, an ample supply is obtainable during nine months of the year.

When a patient falls into labor, she first has her bowels moved by an injection, and then takes a warm bath. The bag of waters is usually ruptured artificially, and the liquor amnii collected in a grocer's scoop. The second stage of labor is never allowed to linger; any delay is met by the use either of the vectis or of the forceps. As soon as possible after the birth and the removal of the child, the placenta is delivered by Credé's method. I may here remark that the still pulsating cord is first cut, then "stripped" of its blood, and as much as possible of its gelatin, and finally tied, when it has ceased to bleed and has become flaccid. Neither belly-band nor any kind of dressing is after-

wards applied, but the cord freely dangles about from the navel. Treated in this manner, it dries up without any bad smell, and falls off like a ripe fruit, without leaving a raw stump. Out of more than five hundred infants treated thus, not one has had a pouting or sore navel requiring treatment, and not one has had an umbilical hernia. I am also well satisfied that, by dispensing with the belly-band, I have had fewer cases of inguinal hernia. Those of my readers who wish a more detailed account of this method of dealing with the cord, can consult the *American Journal of Obstetrics*, vol. iii. p. 327.

Ergot is hardly ever resorted to as an oxytocic; but one teaspoonful of the fluid extract is invariably given as soon as the head presses upon the perineum. When the labor is over, the perineum is examined, and, if torn, is at once sewed up with silver sutures. The patient is now washed clean, and a binder and cylindrical compress applied, the latter in the hollow just beyond the fundus of the womb. The bedstead on which she has been delivered is next wheeled from the delivery-room to a ward and placed along the side of a bed, to which the woman now hitches herself over. Contrary to the generally held opinion that absolute rest after labor is indispensable, in no single instance has this muscular exertion apparently brought about a flooding. It seems rather to condense still further the uterine globe. Very rarely, indeed, has a flooding happened outside of the delivery-room. However warm the weather, a blanket is thrown over the patient, and a foot-warmer put to her feet. These remain until reaction sets in and she asks to have them removed. A mug of beef-tea made from Liebig's extract is now given, and the child put to the breast as soon as it will take it. Thereafter, in a natural convalescence, the woman gets tea, boiled eggs, bread and butter, for breakfast; potatoes, and some kind of meat, for dinner; stewed or fresh fruits, tea, bread and butter, for supper. On the morning following the day of her labor, the binder is removed for good, and she slips into a chair while her bed is making. This is repeated once or twice a day until the fourth or fifth day, when she, if so disposed, gets up and dresses herself. No patient quits her bed against her will; yet the force of example is so great that very few care to stay in bed, when they see their companions up and about.

No woman is allowed to suffer from after-pains. Whenever these are complained of, one-quarter grain doses of morphia are administered every hour until relief is obtained. In stubborn cases of after-pains I have found nothing act so promptly as the exhibition of ten grains of quinia every six hours, until the ears ring. For this valuable suggestion I am indebted to my friend Dr. Fordyce Barker. Bed-pans are not employed, except in cases of illness, or in cases requiring vaginal injections; but each woman has her own chamber-pot, which she uses indifferently, either in the sitting or the knee-elbow posture. Every woman is required to wash her own person at least once a day, and that with carbolic acid soap and a wad of fine oakum, which is at once thrown away. Only under very exceptional circumstances does the nurse cleanse the patient. Should the lochia become offensive, the woman is made to get out of bed and slip into a chair three or four times a day. This usually corrects the fetor; but if it does not, then and only then is a solution of potassic permanganate thrown up into the vagina. Firmly believing the nozzle of a syringe to be the medium of virus communication from patient to patient, I avoid the use of vaginal injections as much as possible. For a like reason, the temperature thermometer is not habitually used, but only in single cases as an aid to diagnosis.

Whenever the lochia are offensive, or the pulse is

over 90, or the thermometer indicates a temperature higher than natural, or pelvic pains are complained of, or, in short, whenever any untoward symptom appears, quinia is given in from six- to ten-grain doses every four hours, until the ears ring. In addition, for abdominal pains large doses of morphia are given, and the whole belly is painted with iodine, and covered with a mush-poultice. The canonical purge on the third day is dispensed with. A patient has usually a movement of the bowels either before or on the day in which she gets up for good. If this does not happen, she takes four Lady Webster's pills at bedtime, which then act on the morning of the sixth day. As soon after getting up as she feels strong enough, she takes a warm bath.

Thus far I have stated the means adopted at the Preston Retreat for the prevention and the treatment of puerperal diseases. I now propose to give my reasons for such of them as need some explanation.

But few words are needed to explain why the ordinary chamber-pots are used, and why patients are made, once or twice a day after the first, to get out of bed and slip into a chair. The presence of putrescent fluids in the utero-vaginal tract is recognized by all writers as the great cause of the autogenetic variety of puerperal disorders. But the recumbent posture of itself necessarily tends to detain these poisonous discharges in contact with the traumatic lesions of labor. These discharges may also be partly imprisoned in the vagina through the swollen condition of the more external soft parts, or partly corked up in the uterine cavity by the presence in the cervical canal of a putrid clot. In such cases detergent vaginal injections are highly recommended. But clinically they will be found of limited value; for they cannot reach high enough, and do not ordinarily dislodge a large clot even when situated low down. True, intra-uterine injections are not open to one of these objections; but, apart from their being attended at best with some degree of hazard to the patient, the operation is too delicate a one to be entrusted to a nurse. Besides, in hospital practice the nozzle of a syringe—to say nothing of the fingers of a nurse—is, I fear, so often one of the vehicles for the transmission of virus, as to make this means of disinfection of doubtful propriety. In a local outbreak of fever, especially of the diphtheritic form, I should, however, suggest the use, immediately after labor, of vaginal injections containing the nitrate of silver or the persulphate of iron, in quantities large enough to sear over the traumatic lesions of labor. Such injections I have had no occasion to try, but they ought to inhibit active absorption and promote healthy granulation.

While seeking a substitute for the syringe, my attention was directed to the fact that the act of sitting on the ordinary chamber-pot often forced out putrid shreds or fetid clots, which had not been washed away by vaginal injections. This led me to discard, except in cases of positive illness, the use of bed-pans or of any other utensil—such as urinals—which can be used by a woman when lying on her back. Shortly after making this change, I found that, for like reasons, some shrewd and very practical writers of the last and the present century urged an early departure from the recumbent posture. Further: a residence of some years in the East had taught me that Oriental women, at least, can with impunity get up and be about a few hours after delivery. Influenced by these facts, I decided, cautiously at first, to introduce into the wards of the Retreat a system of puerperal gymnastics, consisting in no restraint whatever as regards the position in bed, and in the daily release from an irksome confinement. I was much pleased to find that the muscular exertion needed for these movements, so far from inducing hemorrhage, excited the womb to contraction, and emptied it and the vagina of their putrid contents. I

can testify that whenever the lochia are offensive, these upright positions, repeated several times a day, are excellent deodorants, better in fact than any detergent vaginal injections. There is yet another advantage gained by this plan: it affords, in hospital practice, an excellent opportunity for bundling the bed and bedding out of the ward and giving them a much-needed airing. In a crowded hospital-ward the hygienic importance of such repeated disinfection can hardly be overestimated. At the risk of being called an enthusiast, I will go a step further, and hazard the assertion that here is a form of puerperal septicæmia not necessarily accompanied by putrid lochia,—at least not appreciably so,—but indicated by high temperature, rapid pulse, complete anorexia, heavy sweats, and, later, by herpes labialis, which stubbornly resists treatment until the patient is made to get out of bed. This I have seen often enough, after keeping a woman on her back for some pelvic disturbance, to prevent any mistake as to the relation of cause and effect.

Lying-in women are encouraged to get up for good when they feel so disposed, because there are, to my mind, strong objections to the rigorous maintenance of the recumbent posture. Labor is, in general, a strictly physiological process, and there can be no sound reason why it should be made to wear the livery of disease. Nature teaches this very plainly, for most women wish to get up long before their physicians are willing to let them. The fact of a woman's wishing to get up is to me a very good reason why she should get up. In the second place, few physicians will deny that nothing so relaxes the tone of muscular fibre as a close confinement in bed. In my experience a woman ordinarily feels stronger on the fifth day than she does on the ninth, if rigorously kept under quilts and blankets. Once more: the upright position not only excites the womb to contract, but, by distributing the blood and equalizing the circulation, it actually lessens the amount of the lochia and shortens their duration. On the other hand, the dorsal decubitus keeps up a passive congestion of the womb as a whole, the engorgement of the greatly hypertrophied placental site, and a blood-stasis in the now thickened posterior wall,—all important factors in hindering the process of involution. Again: uterine diseases are hardly known among those nations whose women early leave their beds. From passages in the writings of the classics, it is evident that among the ancient Greeks and Romans, those models of physical strength and beauty, the women arose and even bathed in a running stream very shortly after delivery; in some cases, on the very day. Finally: what is sounder than all theory, a sufficiently long and well-sifted experience has proved to me that, by such a treatment, convalescence is rendered far more prompt and sure. At this result, very unexpected to the multiparous patients of the Retreat, they are constantly expressing their surprise.

The arguments against the customary purge on the second or the third day are to my mind very sound. I am well satisfied that the "milk-fever," for which it was originally introduced into practice, is essentially a myth. Genuine "milk-fever," as such, is a rare complication, and, when present, of no significance whatever. Unless the nipples are chapped or abraded, the engorgement of the breasts hardly ever leads to abscesses. In proof of this assertion, how rarely does mastitis follow stillbirths! In the vast majority of cases, the occasional constitutional disturbance, the chill-and-fever on the third or fourth day—the so-called "milk-fever"—is owing to a septic cause, and not to a mammary one. True, the breasts are by this time swollen and painful, but it is a mere coincidence, and coincidence is here mistaken for causation. Purges are, therefore, not only wholly unnecessary, but they disturb the equilibrium,

and, what is worse, promote the absorption of septic matter. Partly from increasing the activity of the absorbents, the hemorrhages of labor are very liable to be followed by blood-poisoning. Now, the same result may be logically predicated of a depletion in the shape of a purge. Were my readers to go over their cases of puerperal fever or of other puerperal diseases, I think that they will find some of them dating from the day on which a purge had begun to act. Is it not more than a mere coincidence that these diseases attack a woman usually on the third or the fourth day—viz., the day of or following the administration of the customary purge? Three instances of puerperal peritonitis, two of them ending in death, have come to my knowledge, which were referable as plainly as could be to purgation. In one, the lady was slowly but surely mending from the effects of a severe instrumental delivery. For some reason or other she took, in the third week, an ordinary dose of citrate of magnesia. This violently purged her, and at once brought on a fatal attack of fever. In the other two the patients could not have been doing better, until they got a dose of castor-oil, which was given for no other reason than that the authors of our text-books were haunted by the bugbear of "milk-fever." Did space permit, I should like to show that this opinion is not shared by myself alone; that cases of phlegmasia dolens have been traced to the effects of a purge, and that the use of aperients during an epidemic of puerperal fever has been strongly condemned.

Quinia is given without stint, because, apart from its well-known tonic and antiperiodic properties, it possesses others which make it, above all remedies, the one best suited for puerperal disorders. By lowering high temperature it retards the oxidation of tissue, and hinders the formation of fibrinous concretions. By shortening the excursions of uterine fibres in their alternate contractions and expansions, it lessens the diastolic engorgement of the womb, diminishes the calibre of uterine blood-vessels, and thereby tends to keep their protective coagula from becoming loose and soluble. By contracting the placental site it proportionally limits that area of absorption. By constringing the coats of the capillaries, and by its inhibitory power over the migration of colorless blood-corpuscles, it either arrests suppurative inflammation or restrains its violence. Finally, it seems to exert a positive curative action on the blood in cases of putrid or purulent absorption. Clinically, I have found nothing comparable to quinia as a prophylactic against puerperal disorders, as well as a remedy for them. But it must be given early, frequently, in large doses, and pushed to a high grade of cinchonism.

Ergot is a very untrustworthy oxytocic. One never can tell beforehand whether it will behave kindly, or run a muck. It is, therefore, no favorite with me. The vectis and the forceps, being under perfect control, are far better oxytocics; their aid is therefore often invoked, in order to save a woman's strength, and to avoid that laxness of uterine fibre following a long and weary labor. Ergot is, however, given as the head is about to emerge, in order to lessen the chances of a flooding or of unruly after-pains, and to aid the process of involution by condensing the uterine globe to its minimum size. For an analogous reason I feel persuaded that Credé's method of placental delivery provokes to a more complete involution. It certainly empties the womb of all clots, and squeezes it down to its smallest capacity.

The prolonged use of the binder is given up, for reasons which have been published in this journal (April, 1874, p. 8). I shall therefore not repeat them. I wish, however, here to state that even its brief use during the first few hours after labor is not held by me as a cardinal point. I begin to have grave doubts

whether it is of any value whatever in the prevention of hemorrhage. On the score of utterly abandoning it I am quite open to conviction.

So much for the reasons on which the foregoing measures are based. Let me now give the results. Up to date there have been 756 cases of delivery, with six deaths. The following are the order and the numbers of the fatal cases, as copied from the Case-Book:

"No. 22. Concealed accidental hemorrhage from the gravid womb. No. 203. Puerperal peritonitis. No. 289. Acute chorea. No. 360. Caries of petrous portion of the temporal bone. No. 398. Chronic pelvic abscess. No. 647. Septic pneumonia."

The case of puerperal peritonitis was an isolated one. The woman had been abandoned by her husband, to whom she was devotedly attached. She fretted and brooded over this desertion in so despairing a manner as to make me apprehensive of mania. Three other patients occupied the same ward with her, but they escaped from contagion.

Cases 22, 289, and 360 were deemed by me so exceptional that their histories were reported to the Obstetrical Society of Philadelphia, and afterwards embodied in its Transactions (*Am. Journal of Obstetrics*, vol. ii. p. 286; vol. iii. p. 140; vol. iv. p. 126). Case 398 was that of an old pelvic abscess following a previous labor—viz., an abortion produced by the kick of a drunken husband. During the last week of utero-gestation this abscess began to inflame and to cause her so much suffering that very large doses of morphia were needed to control it. Labor very greatly intensified this distress. When the womb was emptied a tumor was found in left broad ligament, and all the symptoms of localized peritonitis were present. Under appropriate treatment she soon began to mend; but on the fourteenth day she was suddenly seized with violent abdominal pain, and fell into a collapse, from which she never rallied. An autopsy, made by my friend the editor of this Journal, revealed an old pelvic abscess, which had burst into the cavity of the abdomen. This case, it seems to me, cannot fairly be attributed to a septic cause, but to the ante-partum recrudescence of an old lesion. Case 647 is one of doubt in my mind. There were no appreciable pelvic or abdominal lesions; and yet, in default of an autopsy, which was not permitted by her friends, I think it fairer to attribute the pneumonia to blood-poisoning rather than to a non-septic cause.

To sum up, then,—out of 756 cases of labor there have been 2 deaths from septic causes; 1 death from the bursting of an old abscess; 1 death from hemorrhage; 2 deaths from non-puerperal diseases.

Apart from the above record the Case-Book exhibits no case of phlegmasia dolens, and none of pelvic abscess. One woman, however, had, I am told, a pelvic abscess at home. Through fright at an outbreak of measles in the building, she insisted on rising from her bed and on being discharged on a wet winter night. Although a large proportion of the inmates were primiparæ, and two of them confirmed epileptics, but two cases of eclampsia took place, and these in women who had not been subjected to any prophylactic treatment. The one, while laboring under violent convulsive attacks, was brought in a hack by her friends. The other was seized the day after admission. Both recovered under repeated rectal injections of drachm doses of the hydrate of chloral, and a final delivery under ether with the forceps.

Since nothing is so fallacious as statistics, even when based on large averages, it is with much diffidence that I offer the above meagre data. They may not sustain my views; but they will, I hope, show that lying-in women can be gainfully treated in a manner less artifi-

cial than is customary, and more in accordance with the maxim *naturâ duce*.

One word more: For many reasons the statistics of a lying-in hospital can never compete with those of private practice. Of these I shall adduce but two. In the first place, the former are more trustworthy, for physicians very naturally shrink from reporting their fatal midwifery cases as such. I have known a death from post-partum hemorrhage returned as one from "anæmia," and another from puerperal albuminuria as a case of "pneumonia"—œdema of the lungs being present; whilst fatal cases of puerperal septicæmia are constantly being certified to under the heading of some prominent symptom which tells no tale, such as "peritonitis," "pleuritis," or "pneumonia." For instance, during a period of eight weeks of this year, I was asked to see eight cases of puerperal fever,—four of them from one Sunday to another. Of these all but one proved fatal. During the same time I casually became cognizant of seven other fatal cases. Now, during these eight weeks I studied with much interest the weekly returns of the Board of Health, and found there reported just twelve deaths from "puerperal fever." There were, however, also reported eleven deaths from "inflammation of the peritoneum," one death from "child-bed," and one each from "septicæmia" and "pyæmia." Comment on the above is unnecessary; the figures speak for themselves. In the second place, physicians naturally shirk the worry and anxiety, the delay and trouble incident to difficult labors in their private practice, especially when such occur in a class from which they can expect no adequate remuneration. A hospital thus becomes the Cave of Adullam for all these abandoned cases. For instance, out of the six fatal cases which I have reported from the Case-Book of the Retreat, the one of chorea and that of hemorrhage were sent to the institution by the family physician,—the former on account of her being unmanageable at home, the latter because her labors were growing more and more difficult from an exostosis. The two epileptics* adverted to, two distressing cases of phthisis and valvular disease of the heart, and many of difficult labor in multiparæ, come under the same category. There are at present in the building two women not yet delivered, who were sent there by their respective medical attendants. The one is an epileptic primipara; the other a secundipara with a vesico-vaginal fistula,—the result of craniotomy in her previous delivery. It is thus that the death-rates of lying-in hospitals show to disadvantage beside those of private practice.

GLEANINGS FROM OUR EXCHANGES.

MALARIAL PARAPLEGIA (*The Clinic*, October 3, 1874).—Dr. C. E. Beardsley reports four cases of paraplegia in children from three to five years of age, who were seen twenty-four hours after the first attack. All of them were females, healthy in appearance, well nourished and well clothed. None complained of pain. The temperature was nearly normal. Pulse regular, but a little accelerated. They were cheerful, with good appetite. No difficulty in micturition or defecation. The muscles of the upper extremities were perfect in all of their movements and obeyed the dictates of the will. There was anæsthesia of both lower extremities, with absolute paralysis of all the muscles. The above symptoms were developed suddenly without any known cause, but were accompanied by a piercing cry and loss of motion. One of the cases proved fatal. Spinal

* I am not aware that epilepsy predisposes to puerperal eclampsia—at least I have not found it to do so. But many physicians look upon it as a dangerous complication in labor.

congestion probably existed in all of them, and in two spinal hemorrhage occurred, malaria being the cause in all. The treatment consisted of first a saline purgative, followed by bromide of potassium for some hours with quinia; then quinia alone some hours; finally the galvanic-faradic current.

EMULSION CARNIS.—At a meeting of the Société d'Emulsion pour la Science Pharmaceutique, M. Yvon proposed the following as an excellent form for the administration of raw meat:

R Raw meat, ℥viii;
Sweet almonds, ℥ijss;
Bitter almonds, ℥iss;
White sugar, ℥ijss.

The almonds are blanched, and the whole beaten together in a mortar until a rose-colored homogeneous paste is obtained. This is of an agreeable flavor, and may be mixed with water to form an emulsion, or it may be beaten up with the yolks of eggs, and mixed with milk instead of water.—*Detroit Review of Medicine and Pharmacy*, October, 1874.

Mr. James Kemble, in the *American Journal of Pharmacy* for October, proposes the following very similar formula:

R Fresh raw beef (lean), ℥vi;
Sweet almonds, deprived of their shells and roasted, ℥i;
Bitter almonds, ℥vi;
Sugar, ℥vi;
Glycerin, ℥ii;
Water sufficient for emulsion, ℥i.

Rub or beat the beef, almonds, and sugar to a fine pulp in a wedgwood or wooden mortar, then add water gradually until a smooth emulsion is formed, and strain through a sieve or coarse cloth; return the residuary mass to the mortar, manipulate with the balance of the water until f℥xiv are obtained, strain all through a finer strainer, add the glycerin, and bottle; the bottle is to be kept well corked. Dose, f℥i, containing ℥i of the beef.

The physician, in prescribing, can order the addition of brandy, pepsin, or any other medicine he wishes to administer at the same time.

RATTLESNAKE-POISON (*The Southern Medical Record*, September, 1874).—Dr. S. M. Rivers relates several cases of snake-bite, in one of which death took place within three hours after the reception of the poison. He describes the effects of the poison as those of a narcotic sedative, consisting of an intense burning in the wound, extending over the body, even to the top of the head; vertigo, nausea and vomiting, dimness of vision, irregular spasmodic action of the muscles; then delirium, relaxation, depression of the vital powers, and death by syncope. The only reliable remedy is powerful alcoholic stimulation in conjunction with ligatures above the wound, and suction by means of cups or the mouth directly over it.

MISCELLANY.

FEMALE ARMY-SURGEONS.—The Vienna *Medicinisch-Chirurgische Centralblatt* reports that the Committee of the Society for the care of the Sick and Wounded in War in St. Petersburg has approved of a proposal for allowing women to perform the duties of military surgeons in the field and in stationary hospitals. To carry out the plan it is intended to institute courses of instruction for female army-surgeons (*Feldscheererinnen*) in the Russian universities.—*London Medical Record*.

SLOW PROGRESS OF HOMŒOPATHY IN GREAT BRITAIN.—The *Medical Press and Circular* notices a leading article in the *Homœopathic Review*, in which the latter laments over the unattractiveness of the homœopathic practice, and makes an appeal to its readers to unite in seducing, if possible, the rising generation of the medical profession. The *Review* makes the statement that "of the towns in England above 10,000 and below 20,000 population at the last census, 45 possessed no qualified representation of homœopathy at all, and twelve other towns had only one each; of the towns between 20,000 and 50,000 population, no less than 38 had no resident homœopathist,—14 of them had only one each, and 5 other only two each; of the towns between 50,000 and 100,000, 9 had no homœopathic physician, 7 had only one each, and six others had only two each; while there were, and are actually, 4 towns above the 100,000 limit in which no homœopathist has settled."

The *Review* further says, . . . "Neither can we feel satisfied that our hospitals and dispensaries do at all what they might do in the way of influencing third and fourth years' students. What has London done in this matter with its hospital of sixty beds? What has Birmingham with its well-trying staff and influential committee? What have the Liverpool dispensaries, which admit their 10,000 to 12,000 cases a year? Is it not from these places that our recruits have come, or are coming? . . . The local influence of these institutions on the members of the profession, and on the students in our metropolitan and provincial schools, is practically nil."—*The Medical Record*.

MEDICAL BOARD OF BELLEVUE HOSPITAL.—The following is the Medical Board of Bellevue Hospital as constituted by recent resolutions of the Commissioners of Public Charities and Correction:

Consulting Physicians and Surgeons.—John T. Metcalfe, B. W. McCready, William H. Van Buren, Isaac E. Taylor, Fordyce Barker, Lewis A. Sayre, Alexander B. Mott, and John J. Crane.

Visiting Physicians and Surgeons.—Austin Flint, Sr., James R. Wood, Alonzo Clark, Henry B. Sands, Alfred L. Loomis, Stephen Smith, Wm. B. Eagar, Ernst Krackowizer, Edward G. Janeway, Frank H. Hamilton, Francis Delafield, Thomas M. Markoe, William H. Thomson, Erskine Mason, Gouverneur M. Smith, and John W. S. Gouley.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM OCTOBER 6 TO OCTOBER 12, 1874, INCLUSIVE.

HUNTINGTON, D. L., ASSISTANT-SURGEON.—Assigned to duty as Post-Surgeon at Angel Island, California. S. O. 101, Department of California, October 1, 1874.

PHILLIPS, H. J., ASSISTANT-SURGEON.—To report in person to the Commanding General, Military Division of the Atlantic, for assignment to duty. S. O. 218, A. G. O., October 7, 1874.

LORING, L. Y., ASSISTANT-SURGEON.—Assigned to duty at Camp Apache, A. T. S. O. 86, Department of Arizona, September 18, 1874.

CORSON, J. K., ASSISTANT-SURGEON.—Granted leave of absence for one month, provided he furnish a suitable substitute during his absence. S. O. 161, Department of the South, October 7, 1874.

SATURDAY, OCTOBER 24, 1874.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON SOME AFFECTIONS PECULIAR TO THE FEMALE URETHRA.

BY WILLIAM GOODELL, M.D.,

Professor of the Diseases of Women and Children in the Hospital of the University of Pennsylvania, etc.

THE female urethra, from its shortness, elasticity, and large calibre, is very rarely narrowed by strictures. But it is liable to a class of disorders from which the male urethral canal is almost wholly exempt. The most common and the most painful of these is the one I purpose to show you in the person of this woman.

She is forty-three years old, but constant suffering has made her look much older. In fact, from her great emaciation, care-worn expression, and general cachectic appearance, one might readily suppose her to be the victim of some grave constitutional disease. Her history, in brief, is as follows. Four years ago, while in perfect health, her urine began to scald her. The pain, at first bearable, daily grew worse, until it now is so acute that she holds her water as long as possible, and when passing it clutches the bed-post in her agony. The act of voiding the last few drops gives her the most suffering. Before long, cohabitation became painful, but, with that submissive affection which characterizes many a wife, she yielded to her husband's wishes until it could no longer be borne. For several months she has ceased to have intercourse with him. This is, of course, a source of domestic unhappiness. Unless she stoops and widely straddles her legs, walking is attended with much pain. She complains of a constant heat and throbbing in the external organs of generation, has more or less leucorrhœa, and finds her linen often stained with blood and her urine streaked with it. By brooding over her sufferings and over her incomplete conjugal relations, she has got into a very morbid state of mind. Now, most of these symptoms are so characteristic of some utero-vaginal affection, that the physicians whom she has consulted have been misled to direct their attention to the womb and vagina. Applications have been made to the cervix uteri, which, by the way, is somewhat eroded; vaginal suppositories have been used, and even a pessary has been introduced. What has served still further to lead them astray is a marked sympathetic or reflex pain in the left ovarian region, which is almost always pathognomonic of uterine disease. I ought to do them the further justice to add that they saw her before her sufferings had become as acute as they are at present. Nor can I afford to be uncharitable, for I myself have made the same blunder.

As I separate her thighs and expose the meatus urinarius, those of you on the lower benches can see, peeping out of it, a small crimson and wart-like body. It has received the names of urethral car-

uncle, vascular tumor, and vascular excrescence of the urethra. I seize it with this toothed forceps, and by very gentle traction bring it wholly to view. It now looks like a small Antwerp raspberry, and shows a broad base of attachment just within the lower verge of the meatus. Insignificant in size as this little growth is, it has embittered this woman's life for the past four years. Notice its vascularity: it bleeds on the slightest touch. Remark also its extreme sensitiveness: although profoundly anesthetized, the woman flinches and draws up her limbs. Were she not under the influence of ether she would writhe under the brush of a feather. Let me here remark that the vulva and outlying reproductive organs of a woman are the last to yield to the influence of an anæsthetic. Sensation is here so acute that it will remain long after other peripheral nerves have become benumbed. Thus, in the attempt to pass the hand into the vagina for the purpose of performing version or to introduce a speculum in cases of vaginismus, although the woman may be breathing stertorously, she will often so resist as to need a fresh instalment of ether. I mention this fact not only for your future guidance, but also as a partial explanation of her acute sufferings.

You must not infer that every case of caruncle presents symptoms as exacting as these. In the majority of cases there will be no constitutional implication, and the woman will complain merely of discomfort or of pain during the acts of micturition and of coition. But, on the other hand, worse cases will be met with,—cases in which, by loss of rest, constant suffering, and endless brooding, insanity has been induced. Some women have even been goaded by their anguish to commit suicide. Last autumn I saw a young married lady who was broken down in mind and body by her sufferings. She was peevish, morose, and melancholic, and had dysmenorrhœa and every imaginable ache. Coitus had not been indulged in for months, and she had taken to her bed. Neither her medical attendant nor myself could believe that the presence of a urethral caruncle satisfactorily accounted for pale lips, hollow cheeks, sunken eyes, and for her grave mental and physical manifestations. I sounded her heart and lungs, investigated the condition of her abdominal organs, examined the cervix uteri for a cancer, and finally, I am ashamed to confess, straightened out a somewhat anteflexed womb. Yet, after we removed the caruncle, she became another woman. As if by magic, all her pains and aches, even her dysmenorrhœa, left her. She got out of bed, gained rapidly in flesh, is now an active housekeeper, and, what is more rare, a very grateful patient.

These torturing growths are more common to the married than to the single, and are usually found in women who have passed the prime of life. I am inclined to think that they generally owe their existence to the congestion of the urethral plexus of veins,—such, for instance, as is induced by the pressure of the gravid or the displaced womb, or by the pressure of an over-distended bladder or rectum. In fact, pretty much the same causes are at work

which tend to produce piles. Habits of uncleanness may also generate them, and so may any irritating leucorrhœal discharge. Gonorrhœa is likewise said to be a cause, but I have seen no instance in which they could be traced to this disease. They consist of hypertrophied papillæ covered with a layer of tessellated epithelium, and are largely supplied with nerves and blood-vessels. They may be single or multiple, sessile or stalked, pink or scarlet, and are usually found on the lower verge of the meatus. I have, however, seen them stud the whole circumference of this opening, and occasionally have found them extending up the canal for a distance of half an inch or more. In size they range from that of a pin's head to that of a pigeon's egg, but I have never met with one larger than a good-sized raspberry. The suffering caused by them bears no relation whatever to their size. Very small ones may give rise to intolerable anguish, while a large one may produce merely a sense of discomfort. The more vascular and vivid in color, the more sensitive do they seem to be. Some authors describe a pale, non-vascular, but exquisitely sensitive tumor of the urethra, which appears to be neuromatous in character. This I have never met with. I have, however, twice removed from unmarried girls a worm-like tumor, which dangled from the vestibule. It was pale in color, but seemed to give no discomfort.

Since most of the lesions of the reproductive apparatus, such as vaginitis, uterine displacements, etc., give rise to vesical disturbance, and since the symptoms are not always so typical as in the case before us, a urethral caruncle is very likely to be overlooked by a physician. Reflex symptoms, uterine in their expression, will also tend to lead him astray; while a very natural delicacy prevents him from making the needful visual inspection of the parts. Early in my practice a mortifying blunder of this sort taught me to make it a rule always to inspect the urethral opening whenever dysuria is complained of. But woman's modest nature—nor would we have it otherwise—instinctively resents such an examination. If brusquely proposed, it will almost always be denied. How then is it to be effected? Let me here give you a hint worth knowing. Never suggest to a woman the necessity for making an ocular inspection of her person, but do it without her consent. Let us suppose that you are called in to a case in which dysuria is a prominent symptom. You will very naturally infer the existence of some uterine lesion, and will, of course, ask for an examination with the speculum, to which most women will submit. While exploring the uterus with the index-finger, you may with the thumb press upon the meatus, and notice whether the contact elicits pain. During the introduction or the withdrawal of the speculum you can always visually inspect the parts without the knowledge of the woman. Now, in my experience, whenever you can confidently say to your patient, "I have discovered the cause of your trouble; here it is," and then by digital pressure upon the caruncle can convince her of the correctness of your statement, she will offer no resistance to any future needful expo-

sure of her person. Under all circumstances, however, you must not forget to go through with the formality of covering her with a sheet; for just as you gild and sugar-coat what is bitter to the taste, so must you gild and sugar-coat what is bitter to the mind.

What is the prognosis of this affection? Very good, when the caruncle dangles from the meatus by a slender stalk. Very guarded, when it is sessile or multiple, and especially when it extends up the canal. Like the heads of the fabled hydra,—when ever a sessile caruncle is removed, one or more are very likely to spring up from its stump like mushrooms. Yet even then a cure is usually attainable; while at their worst, as I shall presently show you, their growth can be restrained and the woman made comfortable.

Now comes the final question: What are our resources for the cure of this affection? When distinctly pedunculated, one snip of the scissors is all that is needful for a cure. But when sessile, as they usually are, difficulties arise in their removal which demand the administration of ether and the aid of two assistants.

Let me now illustrate this on our patient. She lies in the lithotomy-position, fronting a good light, and with her knees supported by these gentlemen, who also place their fingers on each side of the meatus and stretch it open. I now seize the growth and carefully remove it by repeated clips of the scissors. I take care to include a portion also of the surrounding healthy mucous membrane. To prevent its otherwise sure return, I quickly dry the raw surface, sear it with the frayed end of a match moistened with fuming nitric acid, and then with a little olive oil decompose any excess of acid. The bleeding was at first quite free, but the acid has, as you see, completely stayed it.

This, however, is not always the case. Three months ago I removed for the second time a cluster of sessile growths, and found at my next visit, twelve hours afterwards, that the lady had lost and was losing too much blood. I staunched the bleeding point with ice and Monsel's salt, and put on a compress with a T-bandage; but at my next visit, six hours later, I found her quite blanched from a recurrence of the hemorrhage. I now ineffectually applied the solid stick of lunar caustic, and then tried to nip the bleeding point with a serrefine, but the tenderness of the part was so great that she would not permit any further interference; nor would she again inhale an anæsthetic. For a moment I was at my wits' end to know what to do. The prospect of spending an hour or two at her bedside, with my finger pressing on the urethra through the vagina, was not an agreeable one. But I finally succeeded by stuffing a sponge half-way into the vulvar opening. Its elasticity and that of the perineum, on which it rested, made the needful pressure upon the bleeding surface.

For avoiding this complication, and also for insuring a complete destruction of the growth, the galvano-caustic loop is undoubtedly the best instrument. But its expense will always put it out of the

reach of those of you who expect to practise in the country. A red-hot knitting-needle could, at a pinch, be used as a substitute.

But it is high time to return to our patient. The after-treatment will consist of the application twice a week of the undiluted commercial carbolic acid (Calvert's No. 4), until the raw surface has skinned over. By the use of this agent I have best succeeded in preventing a crop of small growths from springing up from and around the site of the parent growth. Sometimes you will have to repeat the cutting operation, but not often, if you follow the plan of treatment I have laid down. Once, in an obstinate case, which had passed through several hands and had stubbornly resisted repeated operations, I gained a cure by first cutting off the growth, and then by forcibly dilating the urethral canal with the expanded blades of a dressing-forceps until it admitted my index-finger. I argued that by stretching the muscular coat of the urethra I should release the involved plexus of veins from its spasmodic contraction and thus relieve their congestion. My friend Dr. Theophilus Parvin has succeeded by excising the growth, and bringing the edges of the wound together with stitches. By this procedure the site of the caruncle is covered with healthy tissue, and the chances of its return greatly lessened.

But every woman will not submit to the cutting operation. What then is to be done? Whittle the end of a match to a point, and with it touch each growth twice a week with the crystals of carbolic acid made fluid by heat. This is a very painless operation, and one which you will find very effectual in mummifying the tumor and blunting its sensitiveness. So prompt, indeed, is the action of this acid as a local anæsthetic, that, immediately after its use, I have quietly snipped off the tumor without the knowledge of the woman. For analogous conditions, Dr. A. W. Edis recommends (*British Medical Journal*, April, 1874, p. 449) the use of a saturated solution of chromic acid. It should be applied in the same manner as the carbolic acid, but with more care, and should afterwards be neutralized by pledgets of lint dipped in a strong solution of carbonate of soda. In this relation let me say that during a uterine treatment you will occasionally discover a painless caruncle. If pedunculated, snip it off; but if sessile, be wary of touching it, lest its removal should cause the growth of secondary painful ones.

There are a few other affections of the female urethra, of which I have no examples to show you, but which you will at long intervals meet with. One of them is a granular erosion of the lining membrane, very analogous to that of the cervix uteri. The pain in micturition is excruciating, and the whole urethral tract is tender to pressure made by the finger in the vagina. Upon gently stretching open the meatus, you will find the mucous surface highly congested and denuded of epithelium. This will usually yield to the passage of a pine stick of the size of a catheter, smeared over with undiluted carbolic acid, the urethra being immediately afterwards injected or swabbed with olive oil. This acid

may be boldly applied once a week until the local symptoms disappear. In obstinate cases one application of nitric acid, made in precisely the same manner, will promptly cure your patient. But its use is open to the very grave objection of often causing an obstinate narrowing of the canal, which may make the woman's condition worse than before.

Another affection of the urethra is prolapse of its mucous coat. This usually happens in children, but you will occasionally see it in adults. It is readily told from a caruncle by its less vivid color, by the absence of bleeding, by a low grade of sensitiveness, and by its involving the whole circumference of the meatus. A cure is here attainable either by snipping off a thin strip of the prolapsed mucous membrane, or by one or two applications of nitric acid in a narrow streak around its whole circumference. In either case the cicatrization of the wound will be hastened by subsequent touches with the lunar-caustic pencil.

Very rarely, indeed, will the urethra be the seat of a true polypus. When present, it starts usually from a point high up in the canal, and very generally escapes detection until the patient has passed through several hands. Sometimes it dangles in the bladder, and then stops the flow of urine like a ball-valve. Whenever the act of micturition is obstructed, the physician should search the bladder for a stone, or other foreign body, and, failing to discover one, should dilate the urethra and explore it with his finger. A polypus should be twisted off, or snared in the noose of a double canula. Once removed, it never returns.

A cancer affecting the urethra primarily is a very rare disease. I have seen but one example of it. The woman suffered from obstruction, and I wished to scrape away the growth, but she would not consent, and I lost sight of her. If a removal of the morbid mass is not possible, the most that can be done is to keep the canal open by the daily passage of a catheter and the occasional use of a laminaria tent.

The last affection to which I shall advert is not strictly one of the urethra. I refer to inversion of the bladder through this canal, an accident of which several cases have been reported (*Gazette Médicale de Paris*, January, 1874, p. 8). At first blush this may seem to you an impossible accident; but remember how dilatable is this canal. Through it very large calculi and other foreign bodies have been removed from the bladder. Again, in cases of imperforate hymen, or of absence of the vagina, coition usually takes place through the urethra. The treatment here is to replace the bladder, and to narrow the urethral canal by removing a strip of mucous membrane and by stitching the edges of the wound together.

ALBUMINURIA.—Dr. Girgenson has discovered that the albumen contained in the urine of nephritis differs from that found in cases of accidental albuminuria. The tannin compound of the former contains 37 per cent. of tannin, while that of the latter contains about 20 per cent. The albumen of the blood-serum reacts with tannin in the same way as that of nephritic urine.

ORIGINAL COMMUNICATIONS.

A CASE OF RUPTURE OF THE UTERUS.

BY H. G. LANDIS, M.D.,

Niles, Ohio.

ON the night of September 22 I was called to attend Mrs. O., æt. 34, nativity Ireland, in labor for the tenth time. She had already had four still-births and one instrumental labor, all of them being described as long and difficult. She was a very short, stout woman, with a cleft palate; and her sister, who was her sole attendant, was the subject of a large hare-lip. Labor began at 10 P.M., and yet in three-quarters of an hour the os was sufficiently dilated, and a large bag of waters bulging half-way to the vulva. The anterior lip of the cervix was peculiar, being at least an inch long, as was also the posterior lip; and both were thick and oedematous, and the seat of several old rents. They seemed to hang loosely like a thick fringe from the already dilated os internum. The pelvis was deformed from rickets, the conjugate diameter measuring barely three inches. The vertex presented in the first position. The pains were moderate and the woman very restless, persisting in getting out of bed after nearly every pain, sometimes standing, and often sitting on the chamber. As there was considerable liquor amnii and the "bag" had fulfilled its purpose, I tore the membranes, after which the head forthwith engaged in the superior strait. The pains continued as before, the woman refusing to lie quietly in bed, and the head was stationary. At 2 A.M. of the 23d I sent for the forceps, intending to apply them within an hour more if the head made no advance, as the cervix seemed to be somewhat more oedematous. Shortly after this she lay down, and had two pains of greater force than any before, but not at all violent, aiding them for the first time by pulling on a sheet fastened to the bed-post. Just after the second pain I found the head lower down than before and the sutures overlapping, and was hopeful for a natural termination if the pains continued in this wise. But, in spite of all that could be said, she again arose, and shortly after standing up (at 2.30 A.M.) gave a short cry and complained of a great cramp in the belly. The labor-pains disappeared. There was, however, no shock; no symptom but steady pain. In a few minutes she lay down, when the head was found to have perceptibly receded; the abdomen had also changed in shape, being more uniformly convex instead of the sharply protuberant outline of the uterus before noticed. There was still nothing in the woman's pulse or general condition to warrant the conclusion that so grave an accident as rupture of the uterus had actually happened, but speedy delivery was plainly indicated, so at 2.45 I applied the lower (male) blade of the forceps. It was adjusted with great ease. On introducing the left hand preparatory to applying the upper blade, I found that the head had in the interim ascended an inch or two above the brim. By its side was a hand, ready to present, next to that the placenta, doubled up, and a little farther on was a foot. I at once withdrew the blade of the forceps, and, seizing the foot, turned, which was easily done. During the turning there was a little external hemorrhage. After the delivery of the breech, the head was found to be in an occipito-posterior position, from a pardonable haste in version, and the arms were extended: an unpleasant complication in a contracted pelvis. The arms were with some difficulty brought down, the head remaining at the brim. Morph. sulph., gr. $\frac{1}{4}$, was then given, and at 3.10 A.M., Dr. Leitch having arrived, the forceps were applied, but the disproportion was too great for the head to be de-

livered in a posterior position; neither could I succeed in rotating the head and then applying them. Abandoning the instruments, the head was rotated to an anterior position by pressing the finger against the superior maxilla inside the mouth, the body being simultaneously rotated, after which I pulled down the lower jaw and with moderate traction effected delivery at 3.55 A.M. The child was a male, weighing ten pounds, and of course still-born. The cord was then followed up, and the placenta found in the abdominal cavity, but was easily withdrawn by traction on the cord. I then cautiously explored, and found a rent a little above the junction of the body and neck of the womb, at a point nearly corresponding to the right sacro-iliac symphysis; through it I felt a coil of the small intestines. The body of the womb was firmly contracted, and, being thus pulled away from the uncontracting cervix, made the rent gape somewhat. Notwithstanding all this, the typical physiognomy of shock was still absent, the woman being fully conscious and complaining of excessive pain. At 4.25 A.M. we gave morph. sulph., gr. $\frac{1}{2}$, camphoræ, gr. i, and in an hour began the use of veratrum viride, giving one drop of Norwood's tincture every hour, with morph. sulph., gr. $\frac{3}{8}$, camphoræ, gr. i, every other hour. Her condition remained substantially the same, with little relief from pain except in short doses (the pulse 132 and weak), until 4 P.M., when the pulse was full and inflammatory, but still 132 to the minute. The veratrum was reduced to a drop every other hour. There was scarcely any external flow, but on shifting her from the right side, on which she had hitherto lain, to the left, at her urgent request, a gurgling sound was heard within the abdomen, highly suggestive of effused blood and plenty of it. By 8 P.M. the bowels were much distended and tympanitic; pulse 140; pain not quite so severe; skin moist and hot. Treatment continued, and anointed the bowels with turpentine diluted one-half with lard, reapplying the binder, as it seemed to make her a little less uncomfortable.

September 24.—Made water freely this morning. General condition the same. She was again shifted to the right side. At 11 A.M. called in Dr. D. B. Woods, of Warren, who introduced a drainage-tube into the abdominal cavity, and in the course of the day some thick fluid blood passed through it, not exceeding an ounce. An attempt had been made to place her on her back, but the position was unbearable and caused her to vomit. At 6.30 P.M. the bowels were a little less swollen; pulse 118; not so much pain. The next dose of veratrum was omitted, and it was afterwards reduced to gtt. $\frac{3}{4}$ every hour. Thirst was throughout prominent. She was again placed on her left side. These shiftings were followed by an interval of comparative ease. During the last one the drainage-tube escaped, and, as on her left side it could do no good, it was not introduced till September 25, 8 A.M., when she was again on the right side. At midnight, vomiting began, and she was now unable to retain anything on her stomach. Added acid. carbol., gr. $\frac{3}{8}$, to each dose of veratrum, and bismuth. subnitrat., gr. v, to the morphia and camphor. Morphia placed dry on the tongue was also used, and sinapisms to the epigastrium. From this time medication practically ceased, as the vomiting was persistent and uncontrollable. The fluid ejected was greenish and with little odor. The bowels remained quiescent. Hot cloths were applied to the abdomen, which greatly relieved the pain. By 5 P.M. the features were beginning to look pinched and haggard, the pulse being 124. She survived, however, until 7 A.M. on the 26th. No autopsy could be obtained.

Remarks.—The precise moment of rupture was evidently when the labor-pains were completely abolished and the cramps suddenly began; but it

is not clear whether the placenta became detached immediately. If so, a great deal of blood must have escaped into the abdominal cavity, as the external hemorrhage was slight. In the absence of an autopsy, the precise extent of the rupture is unknown. The suddenness with which the head disappeared from the brim, between the withdrawal of one hand and the substitution of the other, was remarkable. If the second blade could have been applied, the rent would probably have been smaller, but the hemorrhage into the abdominal cavity would have been none the less, and this was undoubtedly the necessarily fatal element in the case. In view of the mortality of this accident, it is a question whether, even after delivery per vias naturales, it would not be justifiable to open the abdomen by an incision and sponge out the effused blood, whose presence is a sure cause of peritonitis, and, by decomposition, of septicæmia. The cause in this case seems to have been premature fatty degeneration of uterine tissue. The pains were throughout comparatively weak, and almost the first attempt at aiding them by voluntary muscular effort resulted in rupture. I was informed that three months before confinement she had had some domestic trouble, during which she fainted, and felt afterwards as if something had given way. The movements of the child, also, became very faint. What this may have been is doubtful. If the rachitic diathesis was an element in the causation, rupture might justly have been expected to occur in former labors; and yet vitality may have been so far impaired that from this very cause the womb was early worn out, so to speak, by frequent use. The influence of rachitis on vitality after the entire cessation of osseous changes is denied very flatly by Parry in his paper published in the *Am. Jour. of the Med. Sciences*, April, 1872, but without the evidence of thorough research that attends the other statements in that valuable paper. It is certainly a debatable question. To sum up: we have here a case of rupture of the uterus occurring after four and a half hours of labor in a multipara with a pelvis deformed by rachitis, followed by death from peritonitis, the first stage of labor having been very short; an obscure history of sudden uterine disturbance three months before; an unusual absence of shock after the rupture, and a subsequent peritonitis in which dorsal decubitus was absent and tenderness of the abdomen slight, as shown by the tolerance of a bandage. The fluid which passed through the drainage-tube most nearly resembled the contents of a cephalæmatoma, which are generally described as loosely coagulated blood. Much of this might have been removed by washing out the abdominal cavity; but the heroic appearance of this procedure, coupled with the almost certainty that equally mischievous clots of large size would still remain, resulted in mere expectancy; and, indeed, decided measures of treatment, to which alone we may look for good in these cases, are likely to be still set aside until the almost millennial day when the physician's hands shall be no longer tied by the demands of popular prejudice.

October, 1874.

TWO CASES OF MYDRIASIS WITH PARALYSIS OF ACCOMMODATION TREATED BY ELECTRICITY.

OCCURRING IN THE PRACTICE OF DR. C. R. AGNEW.

REPORTED BY DR. D. WEBSTER,

New York.

CASE I.—Mrs. G. W. J., æt. 31, married, presented herself for treatment February 17, 1874. She has had no children or miscarriages; has had womb-disease for the last ten years, which her family physician calls ulceration and enlargement. She has been very nervous for years, and has frequent rheumatic pains beneath her shoulder-blades,—worse on the right side. For four or five months she has been subject to severe headaches, more especially in the left temple. A month ago she noticed, for the first time, a blur in reading the newspaper. No history of specific disease.

Examination.—The pupil of the left eye is widely dilated; media and fundus normal; R. E. V= $\frac{2}{3}$; Hm. $\frac{1}{8}$; L. E. V= $\frac{2}{3}$, with + $\frac{1}{30}$. With the left eye she reads Jaeger No. 19, and picks out letters in Jaeger No. 17 at 18''; with + $\frac{1}{12}$ reads Jaeger No. 1 at 12''.

The patient states that she has been salivated; that she has taken potash, and that she is now taking elix. fer. phos. cal. c. strychnia.

I commenced at once the application of electricity—interrupted current. The instrument used was Dr. Jerome Kidder's improved tip-battery. I commenced with the weakest current, applying it at first for only ten minutes. The current was gradually increased in strength until the connections were made at the posts marked A and D, and the tube withdrawn from the helix about an inch and a half, which seemed to indicate the maximum strength that the patient could comfortably bear. The length of time of each sitting was gradually increased until half an hour was reached, and so continued. The positive electrode was generally applied to the closed eyelids, by means of a moistened sponge, while the negative was held in the hand. The electricity was felt much more in the hand than in the eye, unless the sponge happened to be pressed against the supra-orbital or infra-orbital nerve. The application was repeated daily, except Sundays. No improvement was appreciable until after the eighth application, when she read Jaeger No. 15 readily; and now her power of accommodation began to be steadily restored, until, after the twenty-first application, she read Jaeger No. 1 quite easily at 7''. Her pupil became gradually smaller and more responsive to light, until it is now very nearly normal. The patient was discharged, cured, after the twenty-third application.

She remarked that the rheumatic pains beneath her shoulder-blades had entirely disappeared under the treatment.

CASE II.—S. L. W., æt. 27, clerk; first seen January 9, 1874. Four or five days ago found he could not read without closing his left eye, and upon looking into a mirror observed that his left pupil was larger than its fellow. For two days has had several attacks of severe headache. Has had gonorrhœa with bubo for the last month, accompanied by much pain in the perineum. Has had two sores on his penis: the first a year ago, which his doctor said was not a chancre; the other three or four weeks ago, which was caused by an accidental application of tincture of iodine. Gives no history of general syphilis. V= $\frac{2}{3}$ each eye; Em. Fundus and media normal. Unable to read any except the coarsest print, with left eye.

He was ordered to avoid tobacco and alcohol; his habits were regulated, and he was placed on iodide of potassium and tincture of nux vomica. He was kept on this treatment about a month without benefit to his

eye. He was under treatment by an expert for stricture of the urethra at the same time. All medication was stopped, and he was now placed upon electricity, as in Case I. After the ninth application he read Jaeger No. 6 at one foot; after the fourteenth application he read Jaeger No. 1 at 8", but the dilatation of the pupil remained unchanged. The applications were kept up at irregular intervals, so that he had had thirty sittings in all on the 25th of March, when he was dismissed, with still a perceptible difference in the size of his pupils, as also in their mobility. Hypodermic injections of strychnia had been tried in this case, before electricity was resorted to.

It seems worthy of note that in this case the function of the ciliary muscle was fully restored for several days before the sphincter iridis showed any indications of returning strength, while in Case I. the functions of both muscles were restored simultaneously.

ESMARCH'S BANDAGE IN SHOULDER-JOINT AMPUTATION.

BY W. H. MYERS, M.D.,
Fort Wayne, Ind.

RECENTLY, in amputation at the shoulder-joint, I used Esmarch's elastic bandage, as I thought, to a very good purpose. Before the operation I had the arm elevated and the bandage firmly applied, allowing no pressure at the time over the subclavian artery until the bandage was carried up as high into the axilla as possible. Pressure upon the subclavian artery was then applied by an assistant, the bandages removed, and the result was an almost bloodless operation.

PERSISTENT VOMITING OF PREGNANCY—INDUCED ABORTION—RECOVERY.

BY FRANCIS L. HAYNES, M.D.

MRS. C., aged 39, was delivered of her eleventh child January 3, 1873. Shortly afterwards, she was treated for uterine disease—cervical endometritis and a large ulceration of the os—by applications of fuming nitric acid.

On March 1, 1874, a final examination was made: the parts were entirely cicatrized; the canal of the cervix was so contracted that it would barely admit a probe.

Mrs. C. enjoyed perfect health from this time until the latter part of July, when she became aware of the existence of pregnancy from the disappearance of the menstrual flow and the presence of nausea and vomiting, which had been very troublesome accompaniments of her previous pregnancies. The vomiting increasing, medical aid was obtained on August 28. The following drugs were administered in various combinations: quinia, bismuth, cerium oxalat. (in from two- to ten-grain doses), sodium bicarb., potas. bromid., prussic acid, calomel, creasote, and morphia hypodermically, alone and combined with atropia. Nutritious enemata were employed during the entire course of her sickness: without them I am sure she would have succumbed.

In spite of physic, the vomiting became more and more troublesome, until nothing whatever could be retained by the stomach. The patient became very feeble, and assumed a cachectic appearance. The pulse gradually grew weaker and increased in frequency.

On September 10, Dr. Houghton visited the patient, and agreed with me in the propriety of inducing abor-

tion. On the succeeding day a speculum was introduced. No orifice in the uterine neck could be seen, merely a minute depression; into this a probe was forced; its circumference was then nicked by a bistoury; the dressing-forceps were introduced and dilatation practised. This operation was followed by slight alleviation of the vomiting, which, however, soon resumed its usual violence. The patient grew feeble; wandering delirium came on; the pulse rose to 136. On the 15th and 16th she had several severe rigors. To relieve this symptom she was ordered five grains of quinine every two hours by enema.

On the 19th, a sponge-tent was introduced into the cervix uteri; the next morning, Barnes's dilator was applied, and immediately afterwards the uterus was emptied of two fetuses (about six weeks old) and their involucra, by means of the finger and dressing-forceps. To prevent hemorrhage (for there was no contraction whatever of the uterus, either tonic or intermittent), a tampon was applied.

The patient vomited but three times after the abortion, and made a good, though slow, recovery.

FOREIGN BODY IN THE EAR FOR TEN YEARS.

BY CHARLES SHAFFNER, M.D.,

Assistant Physician to the Eye and Ear Institute.

A W., 11 years old, came under our notice September 30. Her mother said that when she was about a year old and living in Ireland, near Londonderry, she was playing out of doors under the care of older children, when one of them brought her in and said she had put a hawthorn stone ("haythorn stone") in her ear. The mother immediately tried to pick it out with a large pin, but not being successful, and it not causing any complaint from the child, she forgot all about it for the time.

It caused very little trouble indeed; occasionally, a slight attack of otalgia, some little tinnitus, described as a low buzzing, and no discharge whatever.

On examination with the speculum, the seed was found against the membrana tympani, surrounded with healthy cerumen. The syringe and Toynbee's forceps assisted us in soon bringing it away, when it was found to be a stony, hard, black seed, about the size and shape of a pea, and was no doubt the seed of a hawthorn tree (*Crataegus oxyacantha*), such as are grown in hedges in Ireland.

The membrana tympani was then carefully examined, and nothing abnormal was discovered but some little congestion,—a very little more than syringing the ear with warm water would naturally produce.

It seems very strange that a foreign body should be so long in such a position without causing severe inflammation and ulceration.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

SERVICE OF J. FORSYTH MEIGS, M.D.

Reported by FRANK WOODBURY, M.D.

A CASE OF ABSENT UTERUS AND VAGINA, WITH RUDIMENTARY OVARIES (P), WITH REGULARLY RECURRING MENSTRUAL MOLIMEN.

THE following are the notes of an interesting case admitted to the Women's Medical Ward on the 14th of August, 1873, during the service of Dr. J. F. Meigs, by whose permission it is reported.

The patient was 22 years of age, born in Germany, and was sent to the hospital with the following history: She had been only four months in America, and had been doing house-work until she was taken sick. One month before admission she caught cold from exposure and overwork, but was able to perform her duties until five days previous, when she was attacked by a very troublesome diarrhœa, preceded by nausea and vomiting, and accompanied by headache, constant fever, and anorexia. The case was pronounced by her attending physician to be one of typhoid fever, and her friends were advised to bring her to the hospital.

There was no fever present when she was admitted, although her pulse was accelerated and it was said that she had been delirious the night before. The tongue was moist, and had a light coating, with red tip and edges. The abdomen was not tympanitic, nor were there any rose-spots visible. The patient seemed well nourished and in good condition, and did not appear to be very ill. She stated that she suffered occasional attacks of severe pain in the right chest and epigastrium. The diarrhœa had become less troublesome than before, but the headache still continued.

The lungs and heart were found to be normal, and the liver and spleen not enlarged.

As the symptoms were not urgent, she was ordered rest in bed, with a light diet, potassii bromid., gr. xx, at night, and a sinapism to the chest if the pain returned.

On the next day the urine was examined, and found to be about the normal quantity and color, neutral in reaction, sp. grav. 1020, and to contain no albumen. The bowels were open once or twice daily, and the fever had disappeared, except a slight flush in the morning following chilly sensations. She was put upon the use of quiniæ sulph., gr. xii, daily, for a week, when it was reduced to gr. vi, and continued after the chills had gone, as a tonic.

The lady with whom she had been living now communicated the fact that although the girl was quite sick every four weeks, she had never had any menstrual discharge, and requested that she might be examined and measures taken for her relief. The patient, who was quite intelligent, said that she came to America in order to learn the language, with the intention of returning at the end of a year and resuming her occupation as teacher in a school kept by her father in North Germany. Her parents were healthy, and she was not aware that a tendency to any special disease or deformity existed in her family. She stated that for more than seven years she had suffered from physical disturbance every four weeks, often being obliged to keep her bed at these periods, but never had any vaginal discharge; a fact to which she did not attach much importance, as another member of her family, an aunt, did not menstruate until after marriage, at twenty-eight years of age. She frequently had epistaxis at these times, which greatly relieved her headache and pelvic distress. On one occasion the family physician ordered an application of leeches to her thighs and abdomen, from which she experienced such relief that she subsequently applied them several times of her own accord. She refused to permit a physical examination while at home, and her physician recommended a visit to America, thinking that a change of climate might encourage the establishment of the function.

In making a digital examination an abnormal condition of the vagina was found. The surrounding parts showed nothing unusual, but the vagina was a cul-de-sac of scarcely an inch in depth.

The next day a thorough examination was made by Dr. Meigs, with the patient under the influence of ether, with the following results:

The patient's frame was large and well developed, and her face full and florid. The mammae were of good size; hips broad. The external parts appeared

rather flattened, but were moderately well supplied by the capilli veneris. The clitoris was of normal size, and the internal labia as usual. By introducing the finger into the rectum, it was found, by the aid of a catheter in the bladder, that the vagina terminated abruptly at the position before indicated, and that no uterus or rudiment of one existed. With two fingers in the bowel a fold of membrane, or band of fibrous tissue, could be felt running across the pelvis, high up, as if it were the broad ligament. There was nothing to represent the uterus, as there was not even a perceptible thickening of the membrane in the centre, but far to the right was found a small, uncertain, movable, local thickening, which gave some resistance, and seemed like a flattened, fibroid body, resembling in size and shape the fibro-cartilage of a large oyster. No corresponding body could be discovered on the left side.

The following day Drs. Ellwood Wilson, James H. Hutchinson, and James C. Wilson were invited to examine the case with Dr. Meigs. Some of the gentlemen thought that the above-mentioned thickening was a rudimentary ovary, and Dr. Ellwood Wilson was under the impression that he felt a similar, but smaller, one on the left side; otherwise they corroborated the former examination.

The patient remained under observation nearly seven weeks, during which she showed marked hysterical symptoms, losing consciousness on several occasions. She had one of her menstrual periods while in the hospital, accompanied by headache, cardiac and lumbar pain, flushed face, etc., but the pulse remained full and slow; she was relieved by the application of leeches to the groin.

The history of the patient since puberty is interesting, as showing the tendency that prevailed to plethora and recurring hemorrhage (*vicarious menstruation?*). The following is an account written by herself at the request of the resident, which was thought worth translating:

"The first half of my fourteenth year was quite free from sickness; then for three or four weeks flushes of heat occurred every evening, and following this bleeding at the nose and abdominal pains (*leibschmerzen*) came on quite regularly *every four weeks*, which still continue. In my fifteenth year I was troubled very much with swollen face and pains in the eyes, and had a severe attack of measles. The next year I had asthma, following the measles, and my limbs were swollen, which still continued during my seventeenth year, but to a greater degree. At this time I commenced to be troubled with rush of blood to the head, so that often my eyes became bloodshot and vision would be temporarily lost. In the succeeding year the swelling in my limbs and feet was so great that I was unable to walk for three months. At this time the doctor applied leeches, but took so much blood that I became weak and had a sense of exhaustion. In my nineteenth year I had chills and fever occasionally quite severely, and had a serious attack of pneumonia. The next year jaundice occurred twice; after the second attack, which was severe, I had an attack of *spitting of blood*, lasting about three weeks. This was followed by anæmia, which continued until my twenty-second (the present) year, when I had two more attacks of pneumonia. . . . When coming on the steamer the second attack occurred, in addition to which I suffered very much from sea-sickness. . . ."

B. D.

To this history may be added the item that the patient was markedly hysterical, having several unmistakable attacks while at the hospital.

It would seem, from what questions could be addressed to her on the subject, that in her sentiments towards the opposite sex she was like other girls of her age.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, OCTOBER 24, 1874.

EDITORIAL.

MEDICAL EDUCATION.

ENCOURAGED by the old saw, A continual dropping will wear away a stone, at the risk of wearying our readers we to-day call attention to the Indiana Medical College as an example of the inevitable results of our American system of medical instruction. In the recent announcement of this college it is stated,—

"The Indiana Medical College was organized in 1869, to meet an educational necessity long felt by the profession of the State. It was formed under a resolution of the Academy of Medicine of this city, and received the unqualified endorsement of the State Medical Society."

At present the college forms the medical department of the State University, and has, therefore, every endorsement of respectability, so far, at least, as the outer world can judge. Yet tuition in it is offered *free*, and attendance only on a single lecture course of about four months' duration is required for graduation. The session opens October 12, and closes on the 26th of February; whilst the official announcement expressly states, "Four years of reputable practice are considered equivalent to one course of lectures."

We note these facts not to complain of them, but simply as beacon-lights; not because the profession in this portion of the country is directly responsible for them, or able to change them, but because they are the legitimate and inevitable fruits of that system of medical education which was fastened upon

the United States by the founders of the Medical Department of the University of Pennsylvania,—a system still supported by the example, if not the precept, of every medical teacher in the East, outside of Boston. We cannot control others, but we can exercise over them the powerful, though it may be unseen, influence of example.

The Medical Department of the University of Pennsylvania was modelled upon that of the Edinburgh University, but in an evil hour the plan was departed from, in that the professor was made a dependent not of the trustees but of the students; receiving his emoluments not from the University but from the class.

Since the University of Pennsylvania has been the foster-mother of the present system, would that it had celebrated its centennial anniversary by stepping up to a higher and nobler plane! It has lost, however, the honor of being the first institution to reform: if it hesitates much longer, it may have the shame of being among the last.

IN what we have said in the past, or may say in the future, on the subject of medical education, we desire it to be distinctly understood that no disparagement is intended of the medical schools of this city, except in regard to the length and amount of study required of the student and the system of granting diplomas.

The corps of medical teachers in this city, public and private, is to-day probably equal to any in the world,—certainly to any on this continent. Medical, surgical, and obstetrical clinicians of ample experience and the highest ability, specialists of the most thorough culture, medical chemists and toxicologists of wide renown, anatomists known wherever science is cultivated, microscopists of skill which may challenge the world, impressive and polished lecturers—we are proud to hold a humble position among such a body of men, and only express our honest conviction when we state that never in the history of our city has so much talent clustered around the medical schools.

The clinical opportunities afforded are also infinitely beyond what they ever have been in the past, and are sufficient to satiate the most avaricious. In West Philadelphia over eleven hundred hospital-beds within five minutes' walk of one another, and very large special dispensary services—for general medicine and surgery, for diseases of the nervous system, of women, of the skin, of the ear, and of the eye—afford material, embarrassing in its richness, for fourteen free clinical lectures a week, and as many private courses as students can be found to pay for.

In the heart of the city, not more than two miles from this medical centre, and with passenger-cars passing to and fro every three minutes, are the large and popular general and special clinics of the Jefferson Medical College, and in close proximity to these the four weekly free clinical lectures of the Pennsylvania Hospital, the oldest institution of the kind in America, and surgically one of the most active hospitals in the world. In the concentration of clinical material and the consequent saving of the time of the student, our city is almost unrivalled, and leaves nothing to be desired.

We find no fault with these facilities, because there is no room for fault-finding. With the finest medical hall on this continent, if not in the world, with progressive teachers and ample clinical and anatomical material, our city offers any one who is desirous of learning every opportunity for the study of the science and the art of medicine, except it be in the one deficiency of a well-appointed physiological laboratory. It is not of these things we complain, but candor forces us to acknowledge with sorrow that any student who does not want so much to learn as to get the title of M.D. and the right to practise, will find in the Philadelphia diplomas the maximum of respectability, with almost a minimum of necessary attainments; not that the standard here is lower than elsewhere,—it is certainly higher than in the smaller schools,—but because it is of very necessity the same or nearly the same as in our neighboring and competing cities. Let us hope that the day is not far distant when a Philadelphia medical diploma will be proof that its possessor is a master in his art, and not, as he may be at present, a mere medical ignoramus.

THOSE of our readers who are subscribers to the *London Practitioner* will be glad to hear that Dr. T. Lauder Brunton is to be the successor of Dr. Anstie. To our thinking the choice is most judicious. We believe Dr. Brunton to be, intellectually, one of the foremost of the London profession.

DR. ANSTIE is stated to have left a family with very slender resources, and measures have been taken to raise a memorial fund, which it is proposed shall be especially applied to the completion of his son's education, the father's plan for which the family are not in a pecuniary condition to carry out.

CHEMICAL and histological laboratories are about being erected in connection with La Charité, Paris, at a cost of over twenty thousand dollars.

A WRITER (*Medical Press and Circular*) styling himself "Cause and Effect" has discovered that abortion is so universally practised in the United States, and "safes" or similar devices used in France, because the law of entail does not exist in those benighted countries.

It is stated that there are a number of "lady students" at the Ecole de Médecine, and that they are on the same footing as the other students.

ROKITANSKY is now seventy years old, but he has been requested by an especial act to continue his lectures on Pathological Anatomy.

DR. WILLIAM RUTHERFORD has been elected Professor of Physiology in the University of Edinburgh.

LEADING ARTICLES.

SECRET POISONING.

A MAN named Moreau, who was accused of having poisoned two wives in less than ten months, by repeated doses of blue vitriol, has been recently tried in France, and the marked contrast between the thorough way in which the medico-legal points were worked up, and the loose manner in which similar subjects have been dealt with in some late trials in this country, warrant a somewhat extended account of the case. Moreau began his education with a view of taking holy orders, but, owing to the partiality for female society which he exhibited, it was soon found that he was unfitted for that vocation. He then went to Paris, where he acquired some knowledge of chemistry, but did not obtain a diploma; and, after marrying a girl with whom he had been living, purchased an herbalist's shop. He became embarrassed in his circumstances, and then, as the prosecution alleged, conceived the idea of poisoning his wife so that he would be free to marry a well-to-do woman, named Lagneau. His first wife died, and he in a short time married the other woman, who was perfectly healthy, and about thirty years of age. She in her turn died not long after her marriage, with symptoms almost entirely similar to those which attended the death of her predecessor. There were many circumstances concerning the deaths of the two women which were calculated to awaken suspicion as to the cause of their death, and the bodies were exhumed and found to contain considerable quantities of copper. Moreau had nursed both of the women during their illness, and had given them their food and medicine, throwing away any which they did not take. He had not summoned the physician who had attended his first wife to care for his second, and to neither of them had opportunity been given to inquire into the cause of

the symptoms under which their patients were suffering.

The second wife, indeed, had expressed the belief that her husband had poisoned her, but he managed to induce her attendant to certify that her death was due to "diphtherial quinsy." The evidence which was brought out at the trial was entirely conclusive, and the prisoner was convicted and sentenced to death.

Dr. Bergeron, who is well known as a medical expert, was directed to exhume the bodies of the two women and examine them, and state whether the conditions which he found could be accounted for by any known disease, or whether they corresponded to those which would be found after the administration of poisonous doses of the salts of copper. The bodies were accordingly dug up, and the autopsies performed at the Morgue of St. Denis. The viscera were removed, with the observance of all possible precautions to prevent anything finding its way into them, and placed in receptacles which were entirely new and clean.

The organs of the first victim were in a wonderfully good state of preservation; they were dry, like parchment, and covered with mould. The condition of the stomach was such that an incision could be made in it as if death had taken place but a few days previously. This organ presented no excoriation nor ulcer, so that the assertion that had been made that death had been caused by some affection of that organ was proved to be without foundation.

The pharynx of the second woman presented no evidence whatever of angina. The coffins were tight, and it was not possible that any copper could have made its way into them and thus have affected the corpses. The most careful tests of the presence of copper in the internal organs were made, and the presence of the metal was established beyond a doubt by bringing it into court. In order to refute the possible objection that copper might be present in all bodies, no less than fourteen bodies were examined, and their viscera tested for the presence of that metal. In two of these cases copper was found to exist in the liver, but in infinitesimal amount, since scarcely one milligramme was detected. The question was then settled, and Bergeron expressed his conviction that the copper found in the intestines of these two women had been administered to them, and that they had died in consequence of its poisonous effects. He further administered the sulphate of copper to two dogs with their food, and at their death found in their livers approximately the same amount of copper that existed in the livers of the two murdered women.

The chemist, M. Lhôte, who had performed these investigations in conjunction with Dr. Bergeron, gave his evidence to the same effect, but in more precise and mathematical language. He testified that in the body of the first woman he had detected one hundred and twenty milligrammes of copper, and in that of the second eighty-four milligrammes of the same metal, and confirmed the statement that in the fourteen bodies which had been tested for copper, it had been found in but two of them, and in quantities of not more than one milligramme.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, SEPT. 23, 1874.

THE PRESIDENT, DR. WM. PEPPER, in the chair.

OVARIAN tumor of the left ovary, and a tubal dropsy of the right Fallopian tube.

Dr. H. LENOX HODGE exhibited the specimen, which was removed at the Presbyterian Hospital from a woman who had suffered from ovarian dropsy for about two years and a half.

She had been tapped eight times by different practitioners, and was admitted into the hospital three weeks after the last tapping. She died on the second day after her admission, in a faint upon rising to have a stool.

Upon making the examination, the uterus was found lying in front of the tumor, flattened and extending three-fourths of the distance to the umbilicus. The uterus was also elongated so as to measure six inches. The tumor extended to the margins of the ribs, and consisted of one large cyst, with a few small ones in the exterior portions of the wall. The large cyst was filled with a thick purulent fluid, with numerous large flakes of fibrinous deposit. Upon its interior were a number of inflammatory growths. The smaller cyst had not suppurated. This tumor was on the left side. The right ovary was healthy, and exhibited a recent corpus luteum. The right Fallopian tube was much elongated, tortuous, and its diameter enlarged, especially towards its fimbriated extremity. This extremity extended far beyond the ovary, and was not in direct connection with it. At the extremity of the tube there was a sac filled with a dark-colored fluid, containing a small quantity of albumen, and communicating freely with and constituting part of the Fallopian tube. The fluid could not be forced along the narrow part of the tube into the uterus.

There was recent local peritonitis, and there was cirrhosis of the liver.

The special points of interest in this case to which Dr. H. directed the attention of the Society were inflammation of an ovarian cyst following tapping; the existence of distinct tubal dropsy; the microscopical and chemical characteristics of ovarian and tubal dropsies.

Specimens of these fluids were sent to Dr. Richardson and to the special committee of this Society of which Dr. Tyson is Chairman.

Dr. JOSEPH G. RICHARDSON said he could not add much to Dr. Hodge's statement. He had found the cells of Dr. Drysdale in the first cyst and in the cyst containing purulent fluid. In the third fluid, decomposition had so far advanced that he was unable to make a satisfactory examination. He had found cells resembling them, but he could not be confident of their characters, because the field was so crowded with bacteria.

Dr. JAMES TYSON said that he had examined, in connection with the Committee on the "Ovarian Cell," three fluids sent by Dr. Hodge said to be of ovarian origin. In one the cell of Dr. Drysdale was clearly present, also in the second, which was pronounced to be pus, while in the third decomposition was so advanced as to admit of no reliable examination.

Dr. RICHARDSON said that while he had treated the cells with acetic acid, he had not applied ether.

Dr. TYSON said that the committee had found the application of ether to the fluids under the microscope so difficult and unreliable, in consequence of its extreme volatility, that they had ceased to attempt to use it in the examination of fluids sent to them.

Dr. RICHARDSON said that during the addition of ether

to the cells on a slide in his presence he had not been fully satisfied that the desired contact took place.

The specimen was referred to a special committee for report, consisting of Drs. Mears, Hodge, and Parry.

Dr. HODGE stated that he joined heartily in the request that the specimen be referred to a special committee for examination, and in reference to Dr. Mears's suggestion that it might be a cyst of the broad ligament which had undergone suppuration, he would call attention to the following facts: The anatomical relations as seen at the post-mortem indicated that it was ovarian. The contents of a small cyst in the wall of the large cyst were highly albuminous.

She had been tapped seven or eight times. Three of these tapings, before suppuration had begun, she described minutely, stating that the fluid was of a greenish color, and coagulated upon boiling, instead of being of the thin, clear, colorless character, like spring-water, so strikingly peculiar to cysts of the broad ligament.

Dr. H. LENOX HODGE also exhibited an ovarian tumor removed by ovariectomy. The operation was performed this morning. The patient is 29 years of age, and has suffered from the tumor for about eighteen months. She was tapped last May, and one large cyst emptied. This was followed by partial relief. During the summer the fluid reaccumulated, and before the operation she measured two inches more around the abdomen than she did before the tapping.

The tumor is of the multilocular form, and belongs to the right ovary. The left ovary was healthy. On account of the thick character of the contents of many of the cysts, and the large amount of fibrous structure, it was requisite to make the abdominal incision ten inches long, extending about one inch above the umbilicus. The patient has reacted well, has no pain, and rests very comfortably this evening.

Congenital imperforation of the duodenum and absence of the gall-bladder.

Dr. RICHARD A. CLEEMANN presented the specimens, and read the following history: "These specimens of morbid anatomy represent arrest of development of the duodenum and of the gall-bladder. They were removed, with the assistance of Dr. C. B. Nancrede, at the necropsy of a female infant, made thirty hours after death. The body was emaciated; the cadaveric rigidity well marked. On opening the abdomen, the *stomach* and what proved to be a portion of the *duodenum* greatly distended were seen, of a pearly whitish appearance, extending quite across from side to side and deep down in that cavity. The contents of this double pouch, to which the stomach contributed about two-thirds, consisted, besides gases, of a thick, blackish-green liquid, resembling meconium: after these were removed the capacity of the whole sac for water was seven and a half fluidounces. Examining the interior of the duodenal portion, a papilla with a central depression is seen, situated posteriorly and near the lower end, but no outlet. A thin strip of tissue has been left, uniting the external face of this little eminence with a narrow blind pouch, which was continuous with the *jejunum*. The latter and the rest of the intestinal canal were contracted, and presented nothing abnormal. The anus, vagina, and urethra were pervious and well formed; the bladder empty. On inspecting the liver, the depression between the right and square lobes is found to be without the gall-bladder, a thin cord of tissue, somewhat expanded anteriorly, occupying this position. Nothing further of special interest was observed in the contents of the abdominal and pelvic cavities; those of the thorax and cranium were not examined.

"The subject of these imperfections seemed, at birth, to be in perfectly good condition, and had in due time alvine and urinary evacuations. However, in the course of the first day, after something fed her by the

nurse, vomiting began, and persisted till the fifth day, when death occurred from exhaustion. The matters vomited at first looked like what had been ingested, but subsequent ejections had a peculiar yellow color, and were at the close quite dark, resembling the post-mortem contents of the stomach, and had a very disagreeable odor. Along with the gastric disturbance, restlessness soon began, and then evidences of pain manifested themselves, which increased till the little patient seemed in an agony of suffering. She ceased to micturate after the second day, but had motions from the bowels to the end.

"The hour-glass-shaped pouch formed by the stomach and part of the duodenum, the much dilated pylorus like a firm ring, making but a loose constriction, had a very deceptive appearance; especially before the immersion of the specimen in alcohol, in which it has contracted unequally. It looked as if the stomach had reverted to the sacculated condition which occurs in some lower animals, and which, indeed, has sometimes been found in infants. In two instances of congenital stricture of the duodenum, reported in the Transactions of the Pathological Society of London (the only cases at all similar to this described there), the shape of the conjoined stomach and part of the duodenum was precisely the same. On the first of these, furnished by Dr. Wilks, the infant died on the second day, fourteen hours after vomiting began, and there were no evacuations from the rectum, the bowels being found distended with meconium at the necropsy. The stricture occurred just above the entrance of the common duct.* In the other case, contributed by Dr. George Buchanan, the child lived eighteen months, presenting a curious succession of symptoms; the difficulty was caused by a slightly oblique septum, with a perforation through the centre only a line in diameter; between the walls of this diaphragm ran the bile-duct.†

"Congenital imperforation in the course of the intestinal canal is much more rare than at its extremities; a fact easily explained by the greater simplicity of development of the walls of the tube than of its outlets. On account of this rarity, little is to be found written on the subject in systematic medical works; but the younger St. Hilaire treats generally concerning it as follows: 'It (the alimentary canal) is sometimes imperfect in one or several regions, principally in its terminal portions, but never throughout its whole length. The imperforation results at one time from a membrane placed transversely, at another from the approach and intimate union of the intestinal walls so that the form of the organ changes from that of a canal to that of a solid cord, and again, finally, from the termination of the intestine in a *cul-de-sac*.'‡ Occurring in the duodenum, as in this case, the condition is of course necessarily fatal.

Absence of the gall-bladder, on the other hand, is not very uncommon, and a compensatory dilatation developing itself in the course of the hepatic duct or in the substance of the liver itself is generally found;§ its non-existence is quite compatible with prolonged life. The conjunction of the two anomalies is, however, very interesting in view of the functional and local relations of the defective organs, to explain which it may be supposed either—following Sir James Paget in the theory which makes one organ in its development serve the purpose of an excretion in the production of another||—that the imperforate duodenum determined the absence of the gall-bladder, or that the close juxtaposition of certain portions of the two organs exposed them to the direct

|| Lectures on Surgical Pathology, third London edit., p. 19.

action of some local disturbing cause. To know what was the condition of the hepatic duct would be useful in this connection, but, unfortunately, the specimen was removed too hurriedly to admit of its dissection.

"As at the necropsy no local condition, such as an adventitious band, was discovered to account for the anomalies, so, with the same negative result, nothing was elicited in the history of the mother's pregnancy to warrant their reference to inheritance, mechanical disturbance, or profound mental impression—the three principal supposed agents in the arrest of development."

The specimens were referred to a special committee for report and drawing, consisting of Drs. Cleemann and John M. Keating.

Two specimens of intestines from cases of typhoid fever.

The PRESIDENT presented the specimens, of which one showed the lower portion of the ileum, with marked enlargement of the glands of Peyer and of the solitary follicles. In a few spots superficial ulceration had appeared. The walls of the bowel were somewhat thickened and too vascular; and there were evidences of general peritonitis, with production of pus and yellowish lymph. The spleen was enlarged; the mesenteric glands enlarged and slightly softened.

The specimens came from a child of four years, who died on the eighth day, of a violent attack of typhoid fever. The early symptoms were obscure and undecided, consisting only of irregular feverishness and failure of strength and appetite. Convulsions occurred on the fifth and sixth days, and the little patient remained subsequently in a state of stupor. The abdomen was much distended, and was evidently the seat of pain. There was no diarrhoea; but when stools were procured by laxatives, they were thin and yellowish.

No cause for the severe peritonitis could be found, as ulceration of the glands of Peyer had in no instance extended deeply enough to cause inflammation of the serous membrane; and there certainly had been no perforation. It is probable, therefore, that it was due to the septic poison of the disease, as is seen in pyæmia, erysipelas, etc. No special source of infection could be discovered at the place where the disease had originated.

Dr. JOHN S. PARRY asked Dr. Pepper whether there had been any temperature-records kept; whether the back had been examined for spots, and whether the stools were characteristic of typhoid fever.

Dr. PEPPER replied that no temperature-record had been kept; that the back had been carefully examined, and that some of the stools were the yellow ochrey stools characteristic of typhoid fever.

Dr. PARRY had seen a number of cases of typhoid fever in children, the youngest being between three and four months old. In this instance there were convulsions, and the child died comatose. There was no peritonitis, but before death the temperature was 109° in the axilla. He had noticed that when the eruption was absent on the abdomen it was sometimes abundant on the back and buttocks. He had always attached great importance to the characteristic alvine discharges after having given a purgative. Further, he was unable to recall many cases of epistaxis, never having seen a severe case in a young child, excepting once, and that was a case of relapsing fever, in which the nares had to be plugged to arrest the hemorrhage.

Dr. PEPPER regretted much that the case was without temperature-observations. It had perhaps happened to every one to notice the great irregularity and obscurity in the symptoms of typhoid fever in children. It is so with regard to epistaxis, the nervous symptoms, and the bronchial complication, which may be entirely absent or attain the degree of a pneumonia; while the

body may be examined from head to foot without finding a trace of eruption, and yet the course of the temperature and the attendant symptoms make the presence of typhoid fever almost a matter of positive demonstration. With regard to the bowels, he could not speak as positively as Dr. Parry. When loose, yellowish stools are present, they are doubtless of great diagnostic value; but doubtless members will recall cases where the bowels are quiet, and where moderate laxatives are borne without the occurrence of the loose discharges, at any rate until too late a period to be of service in diagnosis. The variations in the temperature are so marked and so characteristic as to have secured the name of infantile remittent.

When Dr. Pepper first saw the child it was in convulsions, and it was only by the most careful examination that the history of the case was elaborated. He found that there was chilliness, coldness of the hands and feet, with occasional febrile movement for four or five days previous. Strong purgatives had been administered at the beginning, but there had been no active purgation in consequence, and there was no evidence of irritation sufficient from these purgatives to have produced peritonitis. It is probable, however, that it was the peritonitis which gave rise to the grave symptoms, while there was not sufficient time for the bowel-affection to have progressed to perforation; so that the origin of the peritonitis was constitutional, due to the condition of the blood.

There were open cess-pools in the boarding-house where the family were living, but examination failed to find a sufficient degree of foulness to justify the idea of absorption. There were a considerable number of inmates in the house, but no other case occurred during the summer.

Dr. RICHARDSON said that it had occurred to him that it might be of importance to examine the pus of peritonitis, with a view to finding starch-corpuscles and other ingesta, which would be almost sure to be present after perforation of the intestine had occurred.

The *second specimen* exhibited extreme disease of the solitary glands and patches of Peyer in the ileum, removed from a man twenty-eight years of age, who died in the University Hospital on the twenty-third day of an attack of typhoid fever. He had received no medical treatment until his admission on the twentieth day of the disease, and for four days before that time had been almost without food or attendance. His prostration was extreme; nervous symptoms mild; slight eruption only; considerable bronchial congestion; abdomen distended and tender, and incessant colliquative diarrhoea. The stools ran away from him almost continuously, and were composed of thin, yellowish liquid. All treatment proved unavailing to check this, and death occurred from exhaustion.

At the autopsy, marked pulmonary congestion and decided enlargement of the spleen were found. The mesenteric glands were much enlarged, reddish, and softened. The small intestine was distended, and its walls were vascular. The intestinal glands were implicated throughout the entire course of the bowel, but the lesions were most profound through the ileum, especially towards its lower end. The solitary glands were greatly enlarged, containing semi-fluid exudation, and in some instances had undergone superficial ulceration. The disease of the patches of Peyer towards the lower end of the ileum was extraordinarily intense. The intestine presented, for a distance of more than a foot, a mass of large, oval ulcers, almost confluent, with thick, rounded edges and irregular fungous surfaces.

A case of rupture of the heart, and post-mortem muscular spasms.

Dr. W. W. KEEN presented the specimen, from Mrs. S., æt. 68, who had been in general poor health for some

years, and a year ago had been cautioned as to exertion on account of a fatty heart.

"September 16, 1874, in the morning not feeling very well, and her hands and feet being cold, as her daughter noticed, she did not rise till near noon. Up to this time she had had two or three attacks of vomiting and retching, not more than usually severe, and apparently caused by taking some medicine, as it followed each dose. At 1 o'clock P.M., having been about the room for some time, she said she felt rather worse and would lie down. In a few moments she sat up in bed, retched again, suddenly threw herself back without a word, and was dead. I was hastily called (I had never seen her before), and after listening over the heart and lungs, feeling for the pulse, finding the pupils immobile, and noting the color and coldness of hands, feet, and face, I pronounced her dead. This was some ten or fifteen minutes after death. About half an hour after death, on going into the room, I noticed with surprise that one of the feet seemed to move under the sheet. To assure myself that it was not possibly the shaking of the floor, I uncovered the feet and hands and sat by the body to watch. The movements were not constant, but were very frequent, probably from two to three times a minute at first to once in three to five minutes towards the end, and they did not cease for over an hour and a half after death. They were sometimes spasmodic movements of the whole foot, but by far the most frequent nearly complete flexion of the great toe alone, or of the first two or three toes, or of all of them together. No other part of the body moved. The movements were so marked that I made one or two subsequent examinations to assure myself of the extinction of life.

"The post-mortem was a very satisfactory proof that they were purely post-mortem phenomena.

"*Sectio cadaveris*, forty-eight hours after death.—The rigor mortis was well marked. The subcutaneous fat about one inch thick. The heart only was examined. About eight or ten ounces of clotted blood and serum were taken out of the pericardium. On removing the heart, the valves were competent, as was proved by testing them with water. The aorta and the mitral valves showed the beginning of atheroma, but only slight. The cause of death was found in a rupture in the walls of the left ventricle. The external orifices were mere slits three-sixteenths and one-eighth of an inch long respectively, one-fourth inch apart, one-half inch from the septum ventriculorum anteriorly, and two inches from the apex, respectively. Internally there was but a single opening, hidden completely by the columnæ carneæ, as shown by two probes passed from the exterior. The walls of the right and left ventricles were three-sixteenths and five-eighths of an inch thick, were not fatty to the eye, and were not at all torn or undermined in any way by the rupture. The heart contained no clots save one, quite small, entangled in the columnæ carneæ at the internal opening, and composed of two parts, one half of white fibrin, the other half of more recently coagulated blood. On microscopical examination, the muscular tissue was found very fatty, the striation being firmly visible, however, at most points, but the fibres everywhere broke up longitudinally into fibrils on the slightest violence. The specimen is in the Museum of the College of Physicians."

Dr. PEPPER said that during the short epidemic of cholera which prevailed in Philadelphia a few years ago, he had made several post-mortem examinations. In some of these cases, post-mortem movements of a very startling character had been observed. In some, the insertion of the knife excited distinct twitching movements. He had once or twice observed movements of the arm in sudden death from acute disease.

Dr. HODGE asked how long after death these movements had been observed.

Dr. PEPPER replied that several hours had sometimes intervened. He also alluded to the recent theory on which they were explained as post-mortem changes in the contractile substance of the muscles themselves.

Dr. WILLIAM DARRACH said that about two years ago a lady, apparently in perfect health, walked out of one apartment into another, and in a few seconds was heard to scream. Her friends, on entering the apartment, found her dead. A rupture of the left ventricle of the heart was found in post-mortem examination, and fatty deposits in the walls of the coronary artery. He asked Dr. Keen whether this vessel had been examined in this instance.

Dr. KEEN replied that it had not.

Cast from a bronchial tube.

Dr. J. SOLIS COHEN exhibited a solid cast from a bronchial tube. The specimen had been expectorated in his presence a few days before by a male office-patient, thirty-four years of age, suffering from pneumonic and laryngeal tuberculosis. It was about two inches in length, tapering towards each end; one end being smoothly rounded, and the other having an impress from the angle of a branching tube. It was one-fourth of an inch in diameter in its thickest portion. Atropia was being successfully administered at the time, for night-sweats.

Dr. R. M. BERTOLET said the cast was composed of exudation corpuscles, some organized fibrin, and a few epithelial scales. The latter were much less numerous than usual in these cases.

Wad of paper and cloth removed from lacerated wound of the leg.

Dr. J. E. MEARS presented a mass consisting of paper and cloth, which had been fired from a small cannon, one and a half inches in bore, and which, at a distance of forty feet, produced a lacerated wound of the leg in a patient who was admitted to St. Mary's Hospital.

Fragments of bone from compound comminuted fracture of the skull.

Dr. MEARS presented fragments of bone removed from the frontal bone of a boy æt. 14 years, who had sustained a compound comminuted fracture of the skull, caused by an iron clamp weighing fourteen pounds, which fell a distance of thirty feet, striking the head.

A report of the case appeared in the number of the *Medical Times* for October 3, 1874.

SELECTIONS.

KOLBE ON THE ANTISEPTIC PROPERTIES OF SALICYLIC ACID.

THE physiological action of this substance has been little studied, though its physical and chemical properties are pretty well known. From the fact that it can be readily composed from carbolic acid and carbonic acid, and that, on heating above the boiling point, it is decomposed into these two substances, Professor Kolbe, of Leipsic, was led to expect that, like carbolic acid, it would oppose processes of fermentation and putrefaction, and prove a good antiseptic. Along with Professor Thiersch, he made some experiments in this direction, which he has recently described to the Saxon Academy (see Dingler's *Polytechnisches Journal*, 2d July number).

To ascertain how salicylic acid acted on ferments, he first dissolved some amygdalin in water, mixed with the solution a small quantity of the acid, and added an emulsion of sweet almonds. In a quarter of an hour, by which time a second mixture of almond emulsion

and amygdalin, without salicylic acid, smelt strongly of bitter-almond oil, the mixture containing the acid had not the least trace of such a smell. If the proportion of salicylic acid be very small, the smell will appear after some hours; but, with even a small quantity, no smell will be perceptible after twenty-four hours.

Mustard-seed powder, which in lukewarm water soon gives a strong smell of mustard oil, gives no such smell if a very little salicylic acid be previously mixed with it.

If a solution of grape sugar be mixed with a little salicylic acid (a thousandth at the most), yeast has afterwards no action, and a sugar solution already in fermentation ceases to ferment when a small quantity of the acid is added.

[Details of such an experiment are given.]

Again, some Leipsic beer of excellent quality was divided among several wide glass beakers (1000 grammes to each), and kept fourteen days at a temperature varying between 68° and 75° Fahr., the vessels being covered with loose paper. To one vessel was added (and mixed with the beer) 0.2 gramme of salicylic acid; to a second, 0.4 gramme; to a third, 0.8 gramme; to a fourth, 1.2 gramme; in another glass the beer remained unmixed. This last began at the end of the second day to deteriorate, and became coated with a layer of fungus. In the vessel with 0.2 gramme of salicylic acid the fungus-vegetation commenced on the third day; in the vessel with 0.4 gramme, on the fifth; in that with 0.8 gramme, on the tenth; while the 1000 grammes of beer to which 1.2 grammes of acid had been added did not, even after twelve days, show any fungus-vegetation. Thus, a thousandth of salicylic acid, added to beer, suffices to preserve it from injury through fungus-growth.

Next, fresh and pure cow's-milk, with 0.4 per cent. of salicylic acid added, and left in an open vessel, at a temperature of 64.4° Fahr., was thirty-six hours later in curdling than an equal quantity of the same milk beside it which was without salicylic acid. The addition of a little more salicylic acid delays the souring and coagulation still longer. The milk continues to taste well; the taste of the small amount of acid is not perceptible.

Some newly-passed urine was divided into two portions, and kept several days in separate vessels. A little salicylic acid having been added to one portion, this was found on the third day still clear and free from the smell of ammonia; while the other portion was already far gone in decomposition, and smelt strongly.

Fresh meat, rubbed with salicylic acid, will keep for weeks, in air. The author prepared large quantities of beef and mutton with the acid, put them in a large covered vessel, and a month afterwards he found them still quite fit for cooking. Most of the salicylic acid can be removed by washing, before the use of the meat. The remaining portion has a not unpleasant sweet taste, but it is hardly perceptible.

Professor Kolbe further states that he put hen's eggs, fresh laid in March and April, in an aqueous solution of salicylic acid, and let them lie about an hour in it. After drying, in air, they were laid in a box filled with chaff; in a second box was placed similarly a fresh egg, which had not been impregnated with acid. The eggs will be examined after six, nine, and twelve months have passed, and the results communicated.

Professor Thiersch made some experiments in the Leipsic Hospital as to the antiseptic action of salicylic acid and its use in surgery. He says that when strewn (either by itself or mixed with starch) on contused wounds not yet cleaned and on scurfy gangrenous surfaces, salicylic acid destroys, for a long time, the putrid odor, without any inflammatory action of importance. In solution of one part of salicylic acid, three parts of phosphate of soda, and fifty parts of water, it favors the coating over of granulation-surfaces. As to its action on fresh wounds, the following data are communicated.

During the operation, the wound is kept under a spray cloud of salicylic acid in water (one in 300). The dressing of the wound consists of wadding, impregnated with salicylic acid in the crystallized state. The wadding is moistened with salicylic acid in water (one in 300), as also the strip of muslin by which it is held. Afterwards, a continuous dripping of the acid solution on the bandage, about eight drops in the minute, is maintained. After an amputation of the femur on April 27, under such treatment, the patient experienced no pain, nor swellings, nor fever. The first renewal of the dressing was on the sixth day. The secretion in the wound during these six days was without smell. With equally good results, Dr. Thiersch performed some other amputations. He is of opinion that salicylic acid has all the advantages of carbolic acid, without its inconveniences.

ALEX. B. MACDOWALL.

—*London Medical Record.*

GLEANINGS FROM OUR EXCHANGES.

GUNSHOT FRACTURE OF THE SKULL—TREPHINING—RECOVERY (*The Lancet*, September 19, 1874).—Mr. H. H. Smith reports the case of a man, æt. 20, who attempted to commit suicide by shooting himself in the forehead. When seen immediately afterwards he was quite insensible, and his face was covered with blood, which proceeded from a star-shaped wound in the forehead just above the nose. The wound and the surrounding skin were blackened with powder, and both tables of the skull were visibly extensively comminuted. There was a jagged, irregular opening in the external table of the skull, through which the finger could be easily passed, when it came upon a mass of comminuted bone of the internal table, which was pressing upon the membranes of the brain. His extremities were cold, and his pulse slow; there was no paralysis, and the pupils acted; there was no strabismus.

Mr. Lawson proceeded to examine the wound and to remove all the detached portions of bone and the pieces which were partially broken and pressing on the brain. As the external wound of the frontal bone was much smaller than that of the internal table, two small semi-circular portions of bone were removed by the trephine from above and below the opening in the external table of the skull, and with a pair of dressing-forceps nine pieces of bone and the bullet were lifted away from the surface of the dura mater, which was found to be considerably lacerated. One of the fragments of bone was nearly as large as a florin, and some small pieces of the dura mater came away attached to some of the fragments of the bone. The contused and lacerated integument was then adjusted as far as possible over the wound, and a pad of wet lint, without any disinfecting fluid, was laid over the parts, and kept in position by a strip of plaster.

After about a week of inflammatory trouble the patient began to grow better, and then progressed steadily to complete recovery.

THE ACTION OF MERCURY (*The British Medical Journal*, August 29, 1874).—Dr. James Ross believes that a study of the physical properties of mercury will prepare us to expect that it will have a profound effect upon the body, and that the following may be laid down as general laws, other things being equal: 1. The generality of the effect produced by an agent increases directly as its molecular mobility. Mercury possesses a high degree of molecular mobility, since it is fluid, and volatilizes to a sensible extent at ordinary temperatures; hence it may be expected to produce a very general effect upon the body. 2. The more massive the

molecule of an element, the more defined the action its compounds produce on the parts of the body upon which they act. The molecule of mercury is massive: hence its action may be expected to be not only general, but specific. 3. The salts of those agents which form stable compounds with albuminous substances are retained for a comparatively long period within the body. The salts of mercury form very stable compounds with albumen, and it is known to be retained for a long period.

After absorption, mercury has a preferential action upon the white tissues of the body, more especially the adenoid tissue, which it stimulates to increased activity. It does most good in chronic indurations and effusions. It is used in syphilis during the induration of the primary sore, and in the secondary stage after the fever has subsided. It does no good in the tertiary symptoms, because the disease is then acting on tissues for which mercury has no affinity.

MULTILOCLAR SERO-CYSTIC OVARIAN TUMOR SUCCESSFULLY TREATED BY MEANS OF THE ELECTRO-PUNCTURE (*The Chicago Medical Journal*, September, 1874).—Dr. Plym S. Hayes reports the case of an unmarried woman, æt. 40, who suffered from an abdominal tumor which she had first discovered about four months previously.

The abdomen was as large as that of a woman five months pregnant. The growth extended an inch and a half above the umbilicus when the patient was supine. As the abdominal walls were quite thin, the outlines of the tumor were easily distinguished. Three lobes could be distinctly outlined: one in the right iliac fossa, which had attached to its inferior portion a pedicle passing into the cavity of the pelvis; one to the left of the median line, connected by a band to the first-named lobe; and a third—the original tumor—below this band and just above the pubis: this lobe was felt to be nodule.

Fluctuation could be distinguished in the first two when palpation was employed over each separately, but not when the hand was placed over the one and the other percussed.

Digital examination revealed the fact that the os uteri was directed backward, pressed firmly against the rectum, and congested. Bimanual examination demonstrated that the tumor was not uterine. The sound was introduced into the uterus, and the tumor moved from side to side without producing any marked movement of the sound. The uterus was of normal depth.

Local anæsthesia having been produced by means of ether-spray, two needles were introduced, one into the right cyst, the other into the left, and the current was applied for a few minutes. No trouble followed. This operation was repeated three times during the following month, general electrical treatment being continued during the intervals. No unpleasant effects were at any time experienced, and the treatment resulted in the entire disappearance of the tumor and the complete recovery of the patient.

INJECTION OF MORPHIA INTO A VEIN (*St. Louis Medical and Surgical Journal*, October, 1874).—R. W. Erwin details his own experience on an occasion when he accidentally introduced about one-third of a grain of morphia into a vein, while giving himself a hypodermic injection for the relief of pain caused by a poisoned wound. He was almost instantly seized with a sudden and terrible pressure in the back and basilar portions of his brain. This was of great intensity, and created such a sensation of fullness that he felt as if he would immediately become unconscious; his face was flushed, eyes injected, lips cyanotic, and his skin stung as if pricked with innumerable needles. Applications of cold to the head and neck somewhat relieved these symptoms.

Subsequently there were intense cerebellar headache, general hyperæsthesia of the surface, a severe rigor, and bilious vomiting. Four or five grains of quinine and an ounce of whisky were taken, and about seven hours after the accident the injection was repeated, with the effect of arresting vomiting, relieving pain in the head, and securing sleep. The writer believes that the safest plan of administering a hypodermic injection consists in selecting the part most sparsely supplied with vessels, then gathering up a fold in the fingers, making sufficient pressure at the base to shut off the circulation, after which, slowly injecting the solution. The syringe is then removed, but the pressure is kept up, and only lessened gradually after one or two minutes. This procedure, even should a vein be punctured, will allow of such gradual admission of the drug as not to occasion serious trouble.

EFFECTS OF STAIR-CLIMBING UPON THE HEALTH OF GIRLS (*Detroit Review of Medicine and Pharmacy*, October, 1874).—Mr. George E. Smith, after having investigated the above subject, has concluded that the frequent and excessive climbing of stairs which is rendered necessary by the arrangement of most young ladies' seminaries or colleges is a prolific source of spinal weakness, menorrhagia, etc. He believes, however, that improper dress is really the primary cause of these troubles; tight corsets and heavy skirts rendering any unusual muscular exertion hurtful and dangerous.

A CASE OF CHYLOUS URINE (*The Edinburgh Medical Journal*, September, 1874).—Mr. Robert Smith reports the case of a married woman who, until about two years previously, had enjoyed uninterrupted good health. She then began to be annoyed by a constant pain in the left side, in a position which corresponded to the region and course of the left ureter. There were periods of exacerbation when the pain became acute and was accompanied by sickness. She experienced a scalding extending upwards along the urethra when she voided urine, at the same time that the quantity became diminished; her breath became short, and her ankles swelled towards night. A swelling at the seat of pain became apparent, enlarged, and was very sensitive on motion or pressure. This lasted for some time, until one morning, feeling a temporary relief, she took a walk, which induced a return of her agony. On reaching home she threw herself on her bed, and felt overpowered by a feeling of faintness; then something gave way internally, the swelling in the side subsided, and she soon found herself free from pain, and slept in comparative comfort. The urine next passed looked like thick blood, and contained large quantities of pus; the amount passed after this gradually increased; it was of a dull white color, with a heavy sediment. The œdema disappeared from her ankles, and she was without pain, but suffered from a ceaseless thirst and great weakness, with loss of flesh and appetite. These symptoms gradually progressed, until she died in a comatose condition and greatly emaciated. The urine retained the same character to the last, containing a little fat, albumen, and much pus. The remedy which most diminished the quantity of urine passed was gallic acid, but it was discontinued on account of distressing symptoms which supervened on its use.

TYPHOID FEVER COMPLICATED WITH ŒDEMA OF THE GLOTTIS.—*The Irish Hospital Gazette*, July 15, contains the notes of a case of typhoid fever occurring in the Meath Hospital, in which, during convalescence, that somewhat rare complication, acute œdema of the glottis, occurred, followed by abscess of the larynx. Timely incisions, with external revulsive applications, saved the patient, who was kept alive by nutritive enemata during the progress of the treatment, etc.

MISCELLANY.

MEDICINE AS A PROFESSION FOR WOMEN.—During the last week in August a congress of Danish physicians, more than two hundred in number, met at Aarhus, when, among other points under discussion, the claims of women to enter the profession were brought forward. The congress came to no definite determination on the subject, but it listened with patience to the members who pleaded the cause of female students, and the general feeling at the meeting seemed to be that there was nothing to prevent women from treating the diseases of their sex with ability and success, while in the matter of obstetric practice it was in the highest degree desirable to transfer it completely from the hands of common midwives to those of women duly certificated by the University.—*London Medical Record*.

THE PROFESSION IN EUROPE.—The *Golos* of St. Petersburg states that in Russia there is but one physician to every 17,800 souls. There are governments such as that of Perm, circles like that of Sherdink, where the proportion is still smaller, and there is scarcely one physician to 60,000 souls. There is, moreover, one hospital to every 175,000 inhabitants; one for women in labor to every 6,000,000; one for foundlings to every 1,350,000; one lunatic asylum to every 390,000; one deaf and dumb institution to every 11,000,000. The Russian journal says that the army is better provided for, there being one hospital to every 5000 men. In Prussia the proportion is one to 1250; in Italy there is one physician to every 2280 inhabitants; in England there is one medical man (surgeons included) to every 3180.—*The Medical Press and Circular*.

NOTES AND QUERIES.

4037 CHESTNUT STREET, PHILADELPHIA, }
October 12, 1874.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—I shall be much obliged to you if you can insert the following in your journal:

I am preparing a paper upon *The High or Supra Pubic Operation of Lithotomy*, and, as I desire to have my statistics as accurate and complete as possible, would be glad to receive accounts of any unpublished or inaccessible cases.

The points, of which I desire as many as possible, are—

- I. The name of the surgeon.
- II. The date of the operation.
- III. The sex and age of the patient.
- IV. The size and weight of the calculus.
- V. The result of the operation.
- VI. The time, after the operation, of death or recovery.
- VII. The cause of death, and any remarks as to complications, etc., which may be useful.

Any of your readers who know of cases and will send them will confer an obligation upon

Yours very truly,

CHARLES W. DULLES.

THE following ode gives a witty exposé of the condition of the different schools of philosophy. The refrain is, of course, to be repeated by those who like it, after each stanza:

A DIDACTIC ODE.—*To be sung to the tune of "Guy Faux."*

Ours is a wise and an earnest age, an age of thought and science, Sir;
To error, ignorance, and bliss we fairly bid defiance, Sir.
"Professors" everywhere abound, both in and out of colleges,
And all agog to cram our nobbs with "isms" and with "ologies."

Bow, wow, wow,

Tol de riddle, tol de riddle,

Bow, wow, wow.

Philosophy, as you're aware, material and mental, Sir,
At one extreme is "Positive," at t'other "Transcendental," Sir;
And each of us who in these days would speculate "en règle,"
If he can't run the rig with Comte, must take the tip from Hegel.

The fundamental problem which, debated now for ages, Sir,
Is still attacked and still unsolved by all our modern sages, Sir,
Is, if an effort I may make a simple form to throw it in,
Just what we know, and why we know, and what's the way we know it in.

We can't assume (so Comte affirms) a first or final cause, Sir.

Phenomena are all we know, their order and their laws, Sir;

While Hegel's modest formula a single line to sum in,

Is "nothing is and nothing's not, but everything's becomin'."

"Development" is all the go, of course, with Herbert Spencer,
Who cares a little more than Comte about the "why" and "whence,"
Sir.

Appearances, he seems to think, do not exhaust totality,

But indicate that underneath there's some "Unknown Reality."

And Darwin, too, who leads the throng "in vulgum voces spargere,"

Maintains Humanity is naught except a big menagerie,

The progeny of tailless apes, sharp-eared but puggy-nosed, Sir,

Who nightly climbed their "family trees," and on the top reposed, Sir.

There's Carlyle, on the other hand, whose first and last concern it is

To preach up the "immensities" and muse on the "eternities;"

But if one credits what one hears, the gist of all his brag is, Sir,

That "Erbwürst," rightly understood, is transcendental "Haggis," Sir.

Imaginative sparks, you know, electric currents kindle, Sir,

On Alpine heights, or at Belfast, within the brain of Tyndall, Sir;

His late address, some people hold, is flowery, vague, and vapory,

And represents the "classic nude" when stripped of all its "Draper"-y.

Professor Huxley has essayed to bridge across the chasm, Sir,

'Twixt matter dead and matter quick by means of "protoplasm," Sir,

And to his doctrine now subjoins the further "grand attraction"

That "consciousness" in man and brute is simply "reflex action."

Then Stanley Jevons *will* contend in words stout and emphatical

The proper mode to treat all things is purely mathematical;

Since we as individual men, communities, and nations, Sir,

Are clearly angles, lines, and squares, cubes, circles, and equations, Sir.

George Henry Lewes, I'm informed, had "gone off quite hysterical"

About that feeble, foolish thing, the "theory Metemprical;"

And only found relief, 'tis said, from nervous throes and spasms, Sir,

By banging straight at Huxley's head a brace of brand-new "plasms,"
Sir.

Such are the philosophic views I've ventured now to versify,

And, if I may invent the term, in some degree to "tersify."

Among them all, I'm bold to say, fair room for choice you'll find, Sir,

And if you don't, why then you won't and I for one sha'n't mind, Sir.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM OCTOBER 13 TO OCTOBER 19, 1874, INCLUSIVE.

WHITE, R. H., ASSISTANT-SURGEON.—To report to Lieutenant-Colonel Brooke, Third Infantry, commanding troops in New Orleans, La., for assignment to duty. S. O. 162, Department of the Gulf, October 13, 1874.

CARVALLO, C., ASSISTANT-SURGEON.—Assigned to duty at Fort Stanton, New Mexico. S. O. 166, Department of the Missouri, October 14, 1874.

WOODRUFF, EZRA, ASSISTANT-SURGEON.—To report in person to the President of the Army Medical Board, New York City, for examination for promotion, and, upon its completion, to the Commanding General, Military Division of the Atlantic, for assignment to duty. S. O. 224, A. G. O., October 16, 1874.

SATURDAY, OCTOBER 31, 1874.

ORIGINAL LECTURES.

CLINICAL LECTURE ON SYMPATHETIC IRRITATION.

Abstract of a Lecture delivered at the Hospital of the University of Pennsylvania,

BY WILLIAM F. NORRIS, M.D.,

Clinical Professor of Ophthalmology.

Reported by S. D. RISLEY, M.D., Chief of Dispensary for Diseases of the Eye.

GENTLEMEN,—I desire to call your attention to-day to the subject of *sympathetic irritation*, as being one of the most interesting and important chapters in eye-surgery. It is a fact long observed that where an eyeball has been rendered sightless from inflammation, the result of injuries or otherwise, and is undergoing degenerative changes, it is liable to recurring attacks of inflammation, at which times the other eye may become sympathetically affected.

This of itself is a remarkable fact, and quite contrary to our general experience in other organs; for it is a matter of every-day observation that an inflammation of one hand or foot, for example, no matter how severe or long continued, does *not* usually cause any disturbance in its fellow. There are, it is true, a certain number of accurately observed cases where it has been found that, owing to some not yet thoroughly explained action of the nervous system, inflammation or injury of one side of the body does affect a corresponding area of the other side. This is well shown in the rare and interesting cases of so-called reflex paralysis, or, as some prefer to call it, paralysis from peripheral irritation, following gunshot wounds. Thus, in Circular No. 6, Surgeon-General's Office, for 1864, Mitchell, Morehouse, and Keen report an instance of gunshot-wound of the external side of the left thigh, followed by complete anæsthesia of a corresponding area of the right thigh.

Annandale* also relates a case of wound of a finger, with painful cicatrix and glossy skin, followed by a similar condition of the other hand.

Such instances, as well as the occasional symmetrical disposition of new growths and of cutaneous eruptions on the two sides of the body, although affording abundant food for reflection for the physician, are nevertheless exceptions, which by their paucity rather prove the rule. Unfortunately, however, in inflammations of the ciliary body and iris of one eye we find only too frequently that a similar inflammation develops itself sympathetically in its fellow. And I now propose to study a little in detail the character of the affection so developed, and the circumstances under which it is produced.

In health there is a natural sympathy between the eyes, made evident by the consensual movements of the irides and eyeballs. Thus, all the movements of both globes are in harmony with each other, and

when one eye moves to the right, for example, its fellow makes a similar and equal excursion.

Again, although one eye may be screened from the light, nevertheless its iris will dilate and contract consentaneously with the uncovered eye, as it is exposed to varying light and shade. The same is true of the accommodative efforts. Being thus intimately associated in health, it might be reasonably anticipated that in diseased conditions there would probably be manifested more or less of sympathy between the eyes; and clinical experience proves the inference quite correct. How this conveyance of symptoms from one eye to the other is effected has been the subject of considerable discussion. The first and most natural conclusion, based upon slight observation, was that it was conveyed from the inflamed to the well eye through the intimate relation furnished by the optic commissure; but sympathetic irritation has occurred where there existed complete atrophy of the optic nerves; and, moreover, it is notorious that it does not occur in cases of inflammation of the optic nerve or retina, while it is very frequent in inflammations of the ciliary region. This, as well as other anatomical and physiological observations, makes it probable that it is transmitted through the agency of the ciliary nerves, branches of the trigeminus, or the accompanying filaments of the sympathetic.

This affection has been divided by systematic authors into *sympathetic irritation* and *sympathetic ophthalmia*. Donders and Lawson, indeed, maintain that the one never passes over into the other, but that they are separate and distinct affections, differing in kind. However this may be, the propriety of drawing a marked line of distinction between them is made evident by the clinical history of the disease: the *first* being characterized throughout only by irritation and disturbance of function of the sound eye, which symptoms are promptly arrested by enucleation of the primarily affected one; the *second* by the outbreak of a violent plastic inflammation of the iris and ciliary body of the hitherto sound eye, which at best leaves impaired vision, and is not amenable to any treatment. Even enucleation of the first-affected eye often fails to arrest its march.

Symptoms of sympathetic irritation.—In the first form of the disease, viz., that of irritation at a variable period after injury of one eye, or after the occurrence of an inflammation in an atrophied eye, there sets in an irritation of the sound eye, evinced by an undue sensitiveness to light, increased lachrymation, and an inability to read for any length of time, owing to a failure of the accommodation. The print, when fine, rapidly becomes blurred, and any use of the sound eye brings on pain in the inflamed one. The inflammation in the injured eye usually involves the ciliary region, which is intensely painful on pressure, and is accompanied with a marked pericorneal and ciliary zone of injection, and with the intense neuralgia which accompanies all attacks of irido-cyclitis.

The second form of the disease, viz., *sympathetic ophthalmia*, exhibits, in addition to the above-men-

* Mitchell, *Injuries of Nerves*, p. 159.

tioned group of symptoms, an irido-cyclitis of the hitherto sound eye. There is now a marked ciliary zone, indicative of the inflammatory process going on within the eye. The media begin to lose their transparency, the usual brilliancy of the iris is exchanged for a dull greenish color, from the effusion of plastic lymph into its substance. This is also thrown out upon its posterior surface, and through its agency the iris becomes firmly glued to the anterior capsule of the lens. At the same time floating vitreous opacities may be detected with the ophthalmoscope or by the patient as dark bodies floating in the field of vision. The pupil, bound down to the anterior capsule by layers of plastic lymph, is still further encroached upon by depositions of the same material, which soon entirely block it up, and thus effectually exclude the light and render the eye useless for all purposes of vision.

One of the most marked characteristics of the disease is often a retraction of the periphery of the iris and consequent deepening of the anterior chamber. Sometimes there is an accumulation of fluid behind the iris, and a consequent bulging of portions of it into the anterior chamber. When, after such an inflammation, the eye becomes quiet, it may either be entirely sightless from detachment of the retina and involvement of the choroid, or, the changes having been limited to the anterior portion of the eye, it may still retain a fair perception of light.

Such, gentlemen, is a brief rehearsal of the history of uninterrupted sympathetic ophthalmia.

Let us turn our attention now more particularly to the stage of irritation during which alone you can expect much benefit from treatment. During this first stage of the disease you can promise your patient almost certainly that his uninjured eye will be saved to him, and that the painful symptoms of irritation will be promptly relieved by enucleating the offending eye; to which proposal he will usually submit in order to get relief from the excruciating neuralgia and "weakness" of the other eye, which together prevent sleep at night and forbid any useful employment during the day.

In order that you may have a clearer comprehension of the disease, I will now bring before you an illustrative case which has lately presented itself at the clinic, and in which I purpose enucleating the injured eye in your presence; and will further read in your hearing, from the clinical record we have kept, a few other illustrative cases showing—(1) its relative frequency, (2) the more common modes of its production, (3) its amenability to treatment.

First, then, it is a quite common disease at all large clinics among an industrial population. An analysis of the last twelve hundred cases of eye-diseases presenting themselves at this clinic shows that it constitutes 1.4 per cent. of the whole number. As this number agrees in the main with the percentage of cases falling under my charge at the Wills Hospital (1.3), I suppose it is a fair average, so that you will observe it forms no inconsiderable part of the cases to be treated at a public service.

The most frequent causes of sympathetic ophthalmia are, first, wounds of the ciliary region, especially those followed by prolapse of the iris; secondly, foreign bodies remaining within the eye; and thirdly, degenerative changes taking place in atrophied bulbs. Of these, wounds in the ciliary region are by far the most frequent source of the malady. But in all cases, traumatic or otherwise, its mode of production is by inducing an irido-cyclitis in the one eye, which by sympathy is reflected upon or propagated to its fellow.

As illustrative of this class of injuries, gentlemen, I have selected the case of W. K. from many others in our clinical record. In it several of the leading features of this affection are well marked.

Case I.—William K., æt. 29, *wound of ciliary region.* Patient presented himself at the University clinic, February 1, 1871, having the preceding day received a severe wound of the right eye, inflicted by a piece of glass. It then presented an irregular incised wound of cornea, sclera, iris, and lens, the wound starting above and to the inside in the ciliary region, and extending obliquely outwards and downwards, completely across the cornea, and terminating in the sclerotic as on the other side. The cornea was yet clear; there was some ecchymosis of conjunctiva and lids. One year later he again presented himself at the clinic, when the following record was taken:

Uninjured left eye, $V = \frac{20}{XX}$, and reads Jaeger 1, from 6'' to 16''; right, counts fingers. Bulb is deformed, and presents a broad band-like cicatrix across the cornea. It is tender to the touch, and there is a pronounced zone of ciliary injection. It has been subject to occasional attacks of inflammation, becoming red and painful, at which times he is unable to use his other eye, "because it waters, and the print blurs, and he has severe frontal headache." Ophthalmoscope shows in left eye a healthy fundus, $H = \frac{1}{4}$ central excavation.

In this case, you will observe, we have the important factor in the causation of sympathetic ophthalmia, viz., an injury in the ciliary region. We see, too, that after even so severe an injury the inflammation subsided, and the eye became quiet, so that his visits at the clinic ceased; but a year later he returns with the history of occasional attacks of inflammation in the injured eye, during which the other eye was weak: i.e., it watered when he attempted to use it, and the print soon blurred in consequence of the failure of his accommodation. Here, gentlemen, we have the history of nearly every case of sympathetic irritation following wounds; a variable period of quiet, after which, sooner or later, the eye becomes liable to recurrent attacks of inflammation, and the sympathy of the other eye is manifested in its failure of accommodation and extreme irritability.

The next case presents the same characteristic symptoms to which I have just alluded, viz., the recurrent attacks of inflammation and loss of accommodation in the uninjured eye; but in it you will see a more active inflammation in the injured eye, the pupil blocked up with lymph, the iris greenish, the eyeball softened and atrophied; and another very characteristic symptom, the retracted iris, and consequent deepening of the anterior chamber brought about by contraction of the inflammatory

exudations in and around the ciliary processes and on the posterior surface of the iris itself.

Case II.—C. L., æt. 30; *wounds of ciliary region,—sympathetic irritation.* Two years before applying at the dispensary, June 14, 1872, had been struck in the eye by a fragment of stone, which caused some inflammation and pain. After a few weeks the pain and redness subsided, and he affirmed that his vision was as good afterwards as before the injury. Since, however, he had had repeated attacks of inflammation in the injured eye. And at the date of his first appearance at the clinic we found he had only quantitative perception of light. There was a well-marked scar at upper portion of cornea. The iris, which in the other eye is hazel, in the injured one had become greenish and dull; while a dense yellowish mass of lymph entirely blocked up the pupil. The anterior chamber was much deeper than in the other eye. There was also marked ciliary zone of injection, and the ball was softer than it should have been (T—1.) With the uninjured eye he was able with difficulty to read No. 3 of Jaeger's types at 13'', and that but for an instant, as the eye tired rapidly; but at a distance had, for an instant, nearly the normal acuity of vision,— $V = \frac{20}{xxv}$.

In both these cases, enucleation of the injured eye was followed by a rapid subsidence of the irritation of its fellow. We may have sympathetic irritation set up from other causes than direct injuries or wounds of the ciliary region.

Adhesions between the lids and balls—*symblepharon*—may also give rise to ciliary inflammation and sympathetic irritation, for in every movement of the sound eye the other must also participate; but with every movement to right or left or up or down, there is a pull upon the band of adhesions which is liable to increase the inflammation caused by the original injury in the eyeball.

Case III.—Symblepharon—sympathetic irritation.

H. H. R., æt. 41, a blacksmith, while working at his anvil was struck upon the eye with an iron bolt, which flew up from under his hammer. It struck upon the outside of the upper lid. The accident had occurred five months before he applied at the hospital for treatment. Vision in that eye was entirely destroyed by the inflammation which followed the injury. The upper lid was firmly bound to the ball by extensive adhesions over the ciliary region. He applied for relief not only from the pain in the injured eye, but also complained that for the preceding three months his other eye had annoyed him by flashes of light, and for a few weeks by dark bodies floating in the field of vision. He found that he could no longer read without glasses, and that even with these the print soon became blurred. The ball was enucleated. The patient, after a somewhat prolonged convalescence, regained the good use of his other eye.

The patient before you is one of a similar nature.

Case IV.—W. K., æt. 26; *symblepharon—sympathetic irritation.* Four weeks before applying at the hospital dispensary for treatment (Sept. 8, 1874), had received a splash of slaking lime in his right eye. The ball was found covered with redundant granulations, which encroached upon the entire periphery of the partially opaque cornea. Both upper and lower lids were adherent to the ball, which was soft and sore to the touch. The ophthalmoscope revealed no changes in the sound eye, nor did the examination with the gas-light prove at all painful. He was treated by instilling a solution of the sulphate of atropia.

Two days later, the sound eye became unduly sensitive to light. This has gradually increased until yesterday, ten days after first applying at the clinic, the light of the ophthalmoscopic mirror was blinding, and the examination so painful as to be quite insupportable. The optic disk was now found intensely capillary, and there was slight maceration of the choroidal pigment epithelium. He was advised to part with the injured eye in order to arrest the changes which have already begun in its fellow, and, having concluded to accept the advice, the operation will in a few minutes be performed in your presence.

I have already told you that degenerative changes in a sightless ball frequently lead to sympathetic irritation, and it may be many years after the injury which led to the destruction of the eye, as in the two following cases.

Case V.—J. L., æt. 32; *degenerative changes; formation of bone; sympathetic irritation.* Twenty-two years ago (at the age of ten years), while sledging stone in a quarry, was struck by a splinter in right eye. After healing of wound the ball never gave him any trouble till two years ago, when it became inflamed and painful. Since then the eye has remained more or less sore, at times very red, and intensely painful. Now the right ball is shrunken, and there is no perception of light. There is marked ciliary injection, and it is exceedingly painful when touched. The left eye has vision $\frac{20}{xx}$, but has lately become very sensitive to light; its accommodation is impaired, and all print becomes blurred after looking at it for a few moments. The iris, on shading the inflamed eye, dilates irregularly, moving more freely above and below than to either side, and thus assuming an ovoid shape, but under the influence of atropia dilates regularly and to the maximum. The ophthalmoscope shows that the media are clear, but the disk looks dirty and is hyperæmic.

The ball was carefully hardened, and a section made of it shows a shell of bone between choroid and retina, starting near the optic entrance and extending forward to the ciliary region; and this apparently, by causing inflammation of choroid and ciliary body, had been the cause of the sympathetic disturbance in the sound eye.

Another case where, as many of you will remember, I enucleated the injured eye in your presence, only a week ago, is a good example of the same degenerative change.

Case VI.—E. F. L., æt. 32, when seven years of age lost the right eye by a punctured wound with a pen-knife. Fourteen years later (1865), he had in it a violent attack of pain and inflammation, and since that time numerous other attacks of inflammation, with violent supra-orbital pain. There was marked ciliary injection of the sightless eye, and the upper part of the ciliary region was sore to the touch, as was also a corresponding point of the left eye. He has also in this eye pain after reading five or ten minutes, and it always commences at this spot. The ophthalmoscope shows that it has a hypermetropia of $\frac{1}{4}$ th, that the disk is unduly capillary, and that there is a partial maceration of the choroidal epithelium. A section of the enucleated eye showed a dense sub-retinal shell of bone extending thickest posteriorly, but extending forward into the ciliary region.

There is another item in these cases to which I would particularly call your attention,—viz., that the sympathetic neurosis in the sound eye did not begin until the bony formation had extended forward so as to encroach upon the ciliary body.

Case VII.—S. C., æt. 66; *wound of ciliary region; intra-ocular tumor; sympathetic irritation.* Patient first presented himself at the University clinic in November, 1870, for a painful inflammation of left eye, which had been destroyed by inflammation following an injury six years before. He had lost all perception of light. He stated that at the time of the injury "a small blister" had formed in ciliary region of upper part of the ball, at which point was still plainly visible a puckered scar. The iris was greenish, and the pupil blocked up by a mass of lymph. Eye somewhat shrunken and sore. In right eye $B = \frac{20}{XX}$, and it was not unduly sensitive to light, but soon tired with use. Enucleation was advised, but he did not consent. Two years later (Sept. 1872), he again presented himself at the clinic. The injured eye was red, extremely sensitive to the touch, and for six months had been so painful as to keep him from his ordinary employment as a weaver. In the other eye vision had fallen to $\frac{20}{XL}$; the eye was extremely sensitive to light, and had a well-marked deep ciliary zone of injection. The lids were thickened, their veins distended with blood, and conjunctiva thickened and opaque. The ophthalmoscope revealed marked fullness of the vessels, disk capillary, and extensive maceration of choroidal epithelium; media clear.

Enucleated; four weeks later, the remaining eye had become quiet and painless, and could be used continuously without discomfort.

A section of the hardened eyeball showed, in addition to the inflammatory condition of the ciliary region, a pigmented spindle-celled sarcoma in the posterior part of the ball.

Having seen that any injury or wound of the eye which eventually sets up an irido-cyclitis may give rise to a sympathetic irritation of its fellow, we must not be surprised to find that it is sometimes produced by operations on that organ. That this is the case is evinced by the result of the operation of iridodesis, which was, some years ago, like couching for cataract, quite the fashion. It was a shifting of the pupil by means of a cut just in advance of the ciliary region, into which a portion of the iris was drawn and tied until it became adherent through the healing of the wound. It has been abandoned in consequence of the great liability to the subsequent occurrence of irido-cyclitis and sympathetic irritation. The same may be said of reclination and depression of cataract. This was a most attractive operation, by which the opaque lens was forced from its position behind the pupil down into the vitreous humor and there allowed to remain. It was found that in a large number of cases an irido-choroiditis and cyclitis would be set up by the lens, which acted as a foreign body in the eye, and gave rise to choroidal changes, leading to a slow destruction of the eye, and at times setting up sympathetic irritation in its fellow.

Although more improved methods of operating for cataract afford comparative immunity from these untoward results, nevertheless we do not escape without a certain quota of such cases, as the following histories will show,—one having occurred in my own practice, the other in that of one of my colleagues.

H. L., colored, æt. 32, mother of several children, all of whom are more or less scrofulous, applied for relief in May, 1870, on account of dimness of vision, which had been coming on for over a year. There was complete

opacity in the right lens; that of the left being rather less advanced. The lenses were of a bluish-white color, with saturated, white, rounded spots, and their appearance, together with the age of the patient and the fact that there was a slight arcus senilis and a bluish tinge of the sclerotica, caused the diagnosis of complicated cataract. The perception of light was, however, good throughout the field, and a preliminary iridectomy was done upon the right eye, followed two months later by an extraction of the cataract by the peripheral linear method. The course of the operation and after-healing were normal, and in three weeks she went home with $V = \frac{20}{C}$. In April, 1873, she returned for operation on the left eye. Extraction was performed by the same method without loss of vitreous or other accident, and immediately after the operation patient could readily count fingers. The wound healed well, and nine days afterwards, although the eye was still red, she was discharged at her own urgent request, in order to permit her to wait on her sick husband. A few weeks later she returned to the dispensary, and was furnished with both reading and distant glasses. At this period her vision in the left eye was $\frac{20}{L}$; so good, indeed, that she could see to thread her needle, and learned to spell and read,—an accomplishment which she did not previously possess, the lack of which immediately after the operation had rendered the accurate determination of her vision a work of patience and time.

The eye remained quiet until March, 1874, although she thinks it was always more tender to the touch than that of the other side, when she states that she took cold in it and that it suddenly became red and painful, and on the next day the eyesight became dim. There was intense pain in the supra-orbital and temporal region, which confined her to bed for several days. By the advice of a negro quack, she poulticed the eye with laudanum and powdered cracker, besides taking opium freely internally. Six weeks later, finding that this treatment had not been successful, she again applied at the clinic for relief. At that time the conjunctiva of the left eye was scarlet; there was intense ciliary injection; the iris cloudy and discolored, pupil irregular, and filled with a mass of semi-transparent lymph. It dilated under the energetic use of atropia, but the vitreous was so cloudy that when examined with the mirror no reflex could be obtained from the fundus. The right eye was also beginning to suffer from the inflammation of its fellow; it was unduly sensitive to light, watery; there was supra-orbital pain in that side, vitreous opacities, and a vision of only $\frac{5}{CC}$. The left eye was enucleated, with prompt relief of the supra-orbital pain and a partial clearing up of the vitreous of the right eye.

The second case, H. F., æt. 70, had had the left eye operated for senile cataract two years previously. She had had good vision immediately after the operation, but, on the fourth day after it, severe pain and inflammation set in, eventuating in the loss of that eye. It is now atrophied and shrunken and has lost all perception of light. It has repeatedly been sore and inflamed, and eighteen months after the operation the right eye became inflamed and painful. She has now in it a bare perception of light, and it presents the appearance of an eye lost after a severe attack of serous iritis.

As regards the treatment of sympathetic ophthalmia, Mackenzie long ago pointed out the malignancy of this disease, and its rebelliousness to blood-letting alteratives and the ordinary methods of combating inflammation.

Cutting the ciliary nerves has been proposed and even done; but not only is it objectionable from the difficulty of its performance and the extensive injury inflicted in carrying it out, but we have no security whatever that the divided nerves will not reunite. In fact, gentlemen, there is but one remedy which has stood the test of experience, and that is enucleation of the primarily affected eye. It is simple in its execution, rarely followed by any untoward result, and in the stage of sympathetic neurosis always followed by cure. I think, therefore, that you will have no hesitation in recommending it to your patients. One word of caution in conclusion: insist on rest in bed and low diet for two or three days after the operation; forbid all use of the sound eye for two or three weeks subsequently, so as to give it a fair chance to recover its normal state, and do not allow any artificial eye to be worn till the wound is entirely healed and the stump has become hard and firmly cicatrized.

ORIGINAL COMMUNICATIONS.

A CASE OF DIAPHRAGMATIC HERNIA—THE REMOTE RESULT OF A STAB.

BY A. P. HULL, M.D.,

Montgomery, Lycoming County, Pa.

THE following case may be of interest to some of the readers of your journal:

Mr. R. G. M. T., a young man 31 years of age, of fine physique, and a perfect picture of health, received, on the 7th of January, 1873, a stab over the region of the left lung, which cut off the cartilage of the eighth rib, and, running downward, pierced the diaphragm a little to the left of the œsophageal opening, making an incision about an inch and a quarter in length. The wound soon healed, and after a few weeks he was able to attend to business, and apparently enjoyed good health until May, 1874, when he was seized with a violent attack of colic, which was relieved by the usual remedies.

During June and July he had two more attacks, which lasted two or three days, and it was only with the greatest difficulty that we succeeded in getting his bowels moved.

On Wednesday, the 30th of September, while at stool, he was again attacked with colic, and, every effort to relieve him proving fruitless, he finally died on Thursday, the 8th of October.

Large doses of purgatives were administered, in combination with the most persistent use of injections thrown far up into the bowel through the flexible tube, but without overcoming the obstruction.

At the post-mortem examination which I made, assisted by Drs. Crawford and Lyons, of Williamsport, and Drs. Albright and Wood, of Muncy, on the 9th of October, we found a greater part of the peritoneum and small intestines, and part of the large, in a gangrenous condition, and also a diaphragmatic hernia, a loop of the transverse colon having passed through the opening in the diaphragm and formed extensive adhesions to the lower lobe of the left lung, thus completely obstructing the passage of fecal matter.

NOTE ON THE TREATMENT OF EPISTAXIS.

BY WILLIAM I. WILSON,

Assistant-Surgeon U.S.A.

LATELY I have seen several short articles in the *Medical Times* and other journals concerning the use of persulphate of iron in epistaxis. In February, 1873, I had two severe cases of epistaxis to treat, which I did in the following manner:

I made a solution of the liquor ferri persulphatis, —one part to three of water,—then, introducing the nozzle of the ether-spray apparatus into the nostril from which the blood was flowing, I threw this solution up into the nostril in the form of *spray*, at the same time telling the patient to draw in his breath strongly. The bleeding ceased in a few seconds, and did not again return. The nostril, for a couple of days, was clogged with a hard bloody clot, but at the end of that time it came away naturally.

This, I think, is a much more efficient manner of treating epistaxis than that of plugging the nostrils by a plug of cotton or lint saturated with the solution of the persulphate, or any other method which I have seen mentioned.

FORT BAYARD, N. M.

NOTES OF HOSPITAL PRACTICE.

UNIVERSITY HOSPITAL.

CLINICAL LECTURE ON DISEASES OF THE SKIN.

BY LOUIS A. DUHRING, M.D.

Reported by ARTHUR VAN HARLINGEN, M.D.

ULCERATING SYPHILODERM.

THE case before us is a rare one: you would scarcely find it like anywhere outside of the hospitals of our large cities, and even in these such severe forms of disease are not common. It is an example of the affection usually called syphilitic rupia, a designation which I do not consider quite justifiable, so we will drop this term for the present, and speak of it as simply an ulcerating sphiloderma.

The patient comes before us to-day for the first time, and the only history which we can obtain is that the eruption has existed two or three weeks. Examination shows it to consist of open ulcers and of piled-up crusts of various sizes from that of a split pea up to half a dollar. These crusts and ulcers are scattered over the head, forehead, face, neck, shoulders, arms, and upper part of the trunk; the abdomen, loins, and hips are free, as well as the lower limbs, if we except a large ulcer and crust on the left thigh.

Looking more closely, we observe the reason why there are ulcers in some places and crusts in others: it is simply that in the former case certain ointments have been applied which have macerated the crust and caused it to come away, leaving the ulcer beneath. Bear in mind that the ulcer is the disease, the crust but the product; do not neglect the essential feature.

If we remove any one of these crusts, as I am doing now, an operation which can easily be performed and causes no pain, we see beneath an ulcer, variable in appearance and size. This one you see is quite shallow and granulating, while the other is deep, and its surface is covered with a layer of broken-down products of supuration. It is proper to mention just here that

great care should be taken in handling these ulcers, whose secretion is virulently contagious, and if it were splashed into the face might be productive of serious consequences.

The treatment of a case like this is twofold,—hygienic and therapeutic. This woman requires the very best and most nourishing food,—beef-tea, milk, meat-soups, and the like,—as well as fresh air, and, so far as is possible, moderate exercise. As regards medicine, a tonic is required: one of the bitters, combined, perhaps, with iron in one form or another, and especially in connection with the iodide of potassium, in doses of from five to ten grains thrice daily.

ECZEMA OF THE TOES.

The present trouble has lasted, so the patient tells us, about four weeks. It began a month ago, with itching between the toes, the skin of which after a week became "raw" and "began to run water." Somewhat later, certain abrasions or slight superficial ulcerations showed themselves on the ends of the toes, healing up in a few days and again breaking out. This is the history of the case up to the present time, the treatment having been only slippery-elm poultices and some domestic salve of an irritating quality.

As presented before us to-day, the affection is characterized by redness and swelling, involving several toes of the right foot, together with a certain degree of secretion or moisture, and one or more abrasions on their extremities.

The diagnosis in cases of this kind is not always easy. The question arises, have we syphilis here or a simple eruption of a more specific nature? Is this an ulcerating syphiloderm,—for such are not uncommon in this locality,—or is it an ordinary eczema? Let us examine more closely. Pulling the toes apart and looking at them from beneath with some care, we see where the real trouble is. Here the skin is moist, red, and shining, but there is no ulceration; the affair is quite superficial. Moreover, there is no offensive odor, and this is an important point in guiding our decision. For were this a case of syphilitic disease the odor would be so fetid as to be almost unendurable, and it would resist all attempts at cleanliness; even washing most carefully three or four times a day would not be sufficient to overcome the disgusting stench.

We have then before us a case of eczema, and one of so mild a type that the simplest treatment will, in all probability, be sufficient to bring it to a speedy termination. The patient shall be directed to use a powder of the following composition:

R Zinci oxid.,
Amyli, aa ʒii;
Hydrargyri chloridi mitis, ʒss.—M.

This is to be dusted over the affected parts three times a day; no further treatment will be required.

Do not expect, gentlemen, that all your cases of eczema occurring in this locality will be so easily cured: occasionally you will meet some of an exceedingly stubborn character, when you will be obliged to make use of various stimulating washes, etc., and sometimes will have to resort to internal treatment.

LUPUS.

This woman is about 45 years of age, and has suffered from the disease for which she seeks relief here for nearly thirty years. She says that, so far as she remembers the commencement of the affection, it first made its appearance in the form of a small red pimple like a wart on the left side of the nose, whence it spread very slowly over the entire part in spite of all kinds of treatment. When she first made her appearance here, some six months ago, about two-thirds of the entire nose was the seat of the disease, while the remainder was a cicatricial mass.

The affection had even begun to penetrate the nares, which were nearly closed through the infiltration and subsequent contraction of the tissues.

The patient was at once put upon the use of the iodide of potassium in doses of ten grains three times a day, which she has continued to take up to the present day. About a month ago the application of emplastrum hydrarg. at night was ordered, and under the influence of this course of treatment the amelioration of the patient's condition has been gradual but continuous. But a small portion of the nose is now the seat of morbid action, and we may fairly hope that ere long that also will have entirely disappeared.

FURUNCULOSIS.

This little girl suffers from a trouble which is not at all rare among children, and the diagnosis of which is not difficult. She has, as you see, a number of boils of different sizes scattered over her head, body, and limbs. These are in various stages of progress, some quite hard, indolent, and indurated, others showing signs of approaching suppuration. Here is one on the buttock which is typical; it is large, dark red, very tender to the touch, with an areola reddish, fading away into pink in color, of at least five inches in circumference.

She has suffered from these boils during the whole summer; no cause can be assigned for their appearance; her health is in all other respects quite fair; she does not seem at all broken down.

Cases of this kind are at times very difficult to relieve; they often resist all varieties of treatment with the utmost stubbornness. In this case the patient was ordered Fowler's solution, ℥j thrice daily. She has been taking this about a week, and already begins to look a little better.

ECZEMA OF THE LIP.

This woman has been suffering from papular eczema affecting the fore-arms and arms, while at the same time she has a similar affection of the lower lip. The papular eczema of the arms has disappeared under the treatment, but this disease of the lips still remains.

The form which the eczema took originally in this locality was probably the vesicular, but vesicles appearing on the mucous membranes usually break down rapidly, as they have done in this case before us, and we see merely their bases and remains.

Ecema of the lip is a rare affection, and one very difficult to cure. Situated on a portion of the surface usually bathed in secretions of various kinds, and constantly subject to the irritation of the various ingesta, solid and fluid, it is of course impossible to keep any application in contact with the diseased surface; we must, therefore, have recourse in these cases to internal treatment. The patient before us has been taking for some time the following mixture, under the use of which she is slowly improving:

R Tinct. ferri chlor.,
Acid. phosphoric. dil., aa fʒss.—M.

Sig.—Twenty drops in water thrice daily after meals. Washes containing carbolic acid have been applied to the arms, and have afforded relief.

PENNSYLVANIA HOSPITAL.

SERVICE OF DR. MORTON.

Reported by J. J. KIRKBRIDE, M.D.

CASE OF ABSCESS OF THE KIDNEY, WITH RENAL CALCULUS—DISCHARGE OF THE STONE AND LODGMENT IN THE URETHRA—EXCISION.

J. D., aged 35, was first attacked June, 1872, with intense pain over the left kidney, which lasted a week. During the two or three succeeding days he voided with

the urine a large amount of pus. Six months afterwards he had a similar attack, followed as before by a copious discharge of pus. In three months he suffered in the same manner. The attacks now came on very regularly every three or four weeks, producing great exhaustion. About the middle of last June, while in New Orleans, he had a very severe spell. He left at once, and reached this city on the 29th of same month; was visited by Dr. Cantrell. The urine was loaded with pus, and contained some blood; the former was in amount about one-fourth of the bulk of urine passed; the blood was then observed for the first time. The pus and blood disappeared in a few days. Vesical irritation became a prominent symptom; but he was otherwise in excellent health.

In August he left for the South. On arriving in New Orleans he experienced a sudden obstruction in the urethra, which produced great difficulty in passing water. He came back at once, and on examination, September 1, a large calculus was found impacted in the penal portion of the urethra. Dr. Morton found it impossible to remove the stone with the forceps. An incision was made into the urethra, through which the stone was readily extracted. The wound united by first intention, and the patient has since enjoyed perfect health.

The calculus probably had its origin in the kidney, and from time to time had produced inflammation and abscess; the urethra was thus distended, and the stone was gradually forced into the bladder. The calculus is oval, and of the uric acid variety, and very hard; much resembles a large almond; weighs thirty grains; measures eight-tenths of an inch in length and an inch and a fourth in circumference.

NECROSIS OF THE PATELLA WITH RUPTURE OF THE QUADRICEPS TENDON AT ITS INSERTION, AND OPENING OF THE KNEE-JOINT.

J. A. F., aged 59, was admitted September 19, 1874. Last April had erysipelas of the left leg, ending in ulceration of the skin over the knee, which superficially exposed the upper surface of the patella, and necrosis, with the knee somewhat rigid from the cicatrix, followed. For a long time he has been a sufferer from locomotor ataxia. The day previous to his admission, while walking for the first time since his illness, on attempting to step upon a curbstone the simple bending of the joint caused a transverse rupture of the cicatricial tissue, including the upper surface of the patella, the attachment of the quadriceps muscle, and opening the joint.

September 26. — Severe suppuration having taken place, with pus collecting in the joint, the patella was removed, after dividing the lateral attachments and the ligament.

October 12. — The drain has gradually reduced the patient, causing death from exhaustion.

Treatment consisted in slight extension, sand-bags along the limb, with an anodyne, and supporting regimen.

INCISED WOUND OF NECK, INVOLVING THE LARYNX AND ESOPHAGUS: FOOD INTRODUCED INTO THE STOMACH BY HYDROSTATIC PRESSURE.

F. J., aged 37, was admitted September 30, 1874. While in a fit of temporary insanity he had attempted suicide. The incision was made just above the thyroid cartilages, severing the epiglottis, which remains by its lateral attachments, and the anterior wall of the gullet; the great vessels of the neck escaped injury.

The wound gaped so much that the movements of the vocal cords were easily seen, it being left open, and a gauze covering applied to the front of the neck. By direction of Dr. Morton, a pint of milk, half a pint of beef-tea, with half an ounce of whisky, were administered morning and evening. This was introduced into

the stomach by hydrostatic pressure, instead of the ordinary stomach-pump. To the rubber tube of a nasal douche bottle a stomach-tube was attached, which was passed into the stomach; the bottle containing the food was then elevated above the patient's head, and found to answer admirably, the liquid food flowing slowly and steadily. As soon as the stomach was distended, the patient experienced a regurgitatory sensation, when the tube was at once withdrawn.

This method, which has been faithfully tried in the hospital, is so simple that the old plan of feeding with the pump should be discarded. Should the bottle (the ordinary Thudichum douche vessel) with the opening at the bottom, to which the rubber tube is attached, not be at hand, any vessel may be adapted for the same purpose, the rubber tube being simply held in the fluid and suction made, by which a siphon flow is produced; pressure is made on the gum tube until the stomach-tube is introduced and an attachment made with the tubing, when the vessel will discharge itself.

October 7. — Severe hemorrhage taking place, Dr. Morton ligated the right superior thyroid artery. The next day hemorrhage from the left side was controlled by Monsel's salt with pressure. The amount of nourishment introduced was much increased.

TRANSLATIONS.

INJURIES FROM THE BITES OR STINGS OF SMALL ANIMALS (Dr. M. E. Weiser, *Wiener Med. Presse*, 1874, No. 35). — One morning, in the principal city of Albania, Dr. W. was summoned to see the prima donna of an Italian theatrical troupe which was performing there, and found upon his arrival that she was suffering from some affection of the finger, which increased in severity with such rapidity that she was unable to go on the stage, and was obliged to keep to her bed. The first impression made by an examination of the finger was that it had been attacked by a paronychia, which had spontaneously opened; and this impression was strengthened by discovering, upon inquiring into the history of the case, that there had been a loss of sleep during the previous three nights from the intense pain, which had been at first dull, and, later, throbbing in character. An improvement took place under the use of warm water dressings, to which the treatment had to be limited, since the patient persistently refused to allow an incision to be made; and further examination showed that a similar state of affairs existed upon the other hand. It was then stated by the doctor that it was probable that these affections were caused by the bites or stings of some poisonous animal, and this was confirmed by the entrance of two other members of the troupe, complaining of similar painful swellings in their fingers. It was then found that the members of the troupe had killed many European scorpions and hornets in the foul and badly-kept room upon the floor of which they all slept. On the next day, the "page" of the company, who was the child of the director, was found to be suffering in a similar way. The agreement as to the locality at which the suppuration took place in these different cases was very striking. It was always in the furrow between two of the phalangeal articulations, and upon the volar side of the joint in six of the cases; being upon the dorsal aspect in but one.

In all four of the persons who were the subjects of this accident, the thumb was the part of the hand which was either first or exclusively affected. The trouble lasted about one week, and during the first three or four days the patients suffered severely from pain and loss of sleep. If the affection was left to itself it broke

upon the fourth day, and then, according to its size or depth, resembled either a panaritium in the strict sense of the word, or a simple pustule, of the size of a pea, or perhaps as large as a hazel-nut. This was followed by a sense of relief, and there was soon a real improvement in the state of the patient, manifested by a return of sleep and appetite. The discharge of pus continued of considerable amount, and led to the formation of a loss of substance of circular form, which was but slowly replaced, and left a scar which was visible for a long time. As healing progressed, the epidermis fell off or was removed with the scissors; the newly-formed skin scaled off for some time, and the indurated edge of the cicatrix which was being formed caused much annoyance by the itching which was present in it. At the commencement of this affection it is almost always possible by careful examination to discover a black point, of the size of the point of a needle, situated near the centre of the tumefaction.

In the recent cases in Scutari, Dr. W. thinks that the choice as to their origin lies between the Scorpio Europæus, which is very frequently met with in Turkey, and the hornet (*Vespa crabro*), which is more rarely seen. It is well to be acquainted with the important constitutional symptoms to which lesions of this character give rise, so as not to be deceived by them when their origin is not plainly indicated.

W. A.

TROPHIC AFFECTIONS FOLLOWING CEREBRAL LESIONS.—Dr. A. Muron, in the *Gaz. Méd. de Paris*, September 26, 1874, calls attention to certain trophic affections hitherto undescribed, which may appear in the course of the evolution of cerebral lesions, particularly cerebral hemorrhage. These affections are of two kinds, —external and internal.

Under the term "external affections" Dr. M. includes lesions of the parotid characterized by suppurative inflammation, of the region of the buttocks characterized by a simple congestion of the integuments and subcutaneous cellular tissues, and of the knee characterized by a hypersecretion of synovial fluid.

Dr. M. cites, as belonging to this class, a case in which cerebral hemorrhage into the right corpus striatum was followed six days later by severe inflammation of the parotid, going on to suppuration, which was only cut short by the death of the patient.

At the same time the region of the buttocks on the paralyzed side was observed to be red and vascular, but without pustules or scars, while the corresponding knee was slightly tumefied, and there was probably a certain degree of hydrarthrosis.

Under the term "internal trophic affections" Dr. Muron includes congestion of the kidney of the affected side, and he gives several instances of this class of cases. The first was that of a patient who had suffered a bullet-wound of the brain, involving the middle of the left hemisphere and the third frontal convolution.

Post-mortem examination showed the right kidney considerably enlarged and deeply congested, but without any degeneration of the uriniferous tubules.

A second case is that of a patient 50 years of age, who had suffered two months from left hemiplegia.

Post-mortem examination showed the hemorrhagic clot to have been formed at a point external and posterior to the corpus striatum. The left kidney was found to be at least one-fifth larger than the right, and much firmer in consistency, while very decided congestion was evidently present. That this congestion was recent was shown by the absence of granular fatty degeneration of the uriniferous tubules, while the cellulules of the capillaries were more or less completely infiltrated with numerous pigment-granules. Other cases of a similar nature are referred to, and the paper is concluded by a description of a case of clinical

interest, in which cerebral hemorrhage followed by left hemiplegia without loss of intelligence was accompanied by temporary albuminuria. This latter disappeared with the gradual amelioration of the paralysis.

A. V. H.

THE INFLUENCE OF MERCURY ON THE RED AND WHITE BLOOD-CORPUSCLES.—Dr. Wilbouchervitch, of Moscow, publishes the results of a series of experiments on this subject in the *Archives de Physiologie*, July-September, 1874.

After giving the details of a large number of carefully performed experiments, Dr. W. states his conclusions as follows:

1. Mercurial preparations in small doses produce during a certain period, in individuals affected with syphilis, an increase in the red globules of the blood, and at the same time a slight diminution in the number of white globules (hypoglobulie). The diminution in quantity of the blood-globules due to the syphilitic disease is arrested, and the blood returns to its normal condition.

2. Too long continued mercurial treatment gives rise to the same conditions as when the drug is administered in large doses; that is, it brings about rapidly, in animals, hypoglobulie, diarrhoea, etc.

3. Consequently, it is very important to know exactly at what moment the mercurial treatment should be suspended, and this moment can only be ascertained by enumeration of the blood-globules.

4. It is necessary, then, to divide the mercurial treatment into several periods. At first, that condition of hypoglobulie which coincides with the early manifestations of syphilis should be combated by mercurial preparations in small doses until a diminution in the number of red globules is noticed. At this point treatment is suspended until hypoglobulie again occurs. Then mercury is once more administered, and this is again suspended when diminution of the red globules is once more reproduced.

Dr. W. concludes by stating that he has only observed thus far the influence of mercury in the primary lesions of syphilis. The study of the same influence in secondary and tertiary lesions he leaves until some future occasion.

A. V. H.

UNION BY THE FIRST INTENTION FOLLOWING A WOUND MADE BY A CIRCULAR SAW.—The case occurred at the Hôpital Cochin, under care of M. Despris, and is reported in the *Gaz. Hebdom.*, September 25. The patient was wounded in the right index-finger by a circular saw, the incision being made so sharply that the articulation of the third phalanx was opened without the bones having been injured.

The wound was so deep that only a posterior flap remained uninjured. There was very little hemorrhage, and the wound was hermetically sealed by means of strips of diachylon plaster, which were continued to the root of the finger.

The next day the wound was examined, when it was found that no blood had escaped from under the strips of plaster; some pain was experienced. On the third day the pain was more severe, but the plaster strips were retained in position. On the fourth day union had taken place, but the strips were prudently allowed to remain a week longer.

At the end of that time they were removed. The wound had closed without a drop of suppuration, leaving a linear scar. Movements of the finger at first caused pain, which gradually disappeared.

A. V. H.

CAUSES OF DEATH OCCURRING AFTER THE ABLATION OF NASO-PHARYNGEAL POLYPI.—Dr. Pozzi read at the recent meeting of the Association Française (*Gaz. Méd.*,

September 26) a memoir relative to observations made in the service of Professor Verneuil. A patient suffering from a nasal polypus, and who had been operated upon for the second time on account of a return of the disease, supported the operation without any unusual symptoms, but died suddenly after having been replaced in his bed. The author adds other cases of similar nature and terminating fatally, where, as in this instance, destruction of the inferior wall of the cranium was observed, with thinning, fissures, and perforations, through which prolongations of the polypus passed in to the brain.

Death supervened unexpectedly, and by syncope, within a few hours subsequent to the operation, though there had been little loss of blood, and no accident of any kind followed the procedure.

M. Pozzi thinks that thinning of the base of the cranium and the connections of the polypus with the brain may predispose to syncope and sudden death. And on the other hand he has learned by experience that hemorrhages in the carotid or cerebral systems are much more quickly followed by death than in the case of hemorrhages from the arteries of the trunk or members, even where the loss of blood may be less. A. V. H.

PAINFUL ANGIOMATA.—At the same meeting, Prof. Trélat made some remarks on these tumors. Angiomas differ from the tumors called erectile, which should be called cavernous angiomas; the simple variety only contain blood-vessels. Formerly, when a small tumor was painful, it was called a neuroma; but painful neuromata are very rare, while indolent tumors of the nerves are quite common.

Prof. Trélat cited three cases of very painful tumors supposed to be neuromata, but which were afterwards found to be purely vascular; two were subcutaneous, one was submucous and existed at the vaginal orifice. In these three cases ablation was practised, which was followed by cure. Again, a case was cited where severe pain was caused by contact of the median nerve with vicious callus of the bones of the fore-arm; the nervous surface which had been in contact with the bone had become smooth, flattened, and of a ganglionic appearance. Resection of a part of the diseased nerve, resection of the bone, and re-setting the member, were followed by immediate cessation of pain and rapid cure. A. V. H.

SURGICAL TREATMENT OF OZENA WITHOUT PRODUCING DEFORMITY OF THE FACE.—Dr. Rouge, of Lausanne, has devised and executed the following operation. The patient being placed under the influence of an anæsthetic, the head inclined to the right, the upper lip is raised as high as possible. The gingivo-labial ridge of the first molar is then, on the right, incised to the left. All the tissues being divided, the anterior nasal spine is reached, and then the septum is detached from its base.

It is now possible to introduce the finger into the patient's nose and to explore the nasal fossæ.

If necessary, a still larger way may be opened by dividing the cartilages of the *alæ nasi* at their maxillary insertions.

In nine cases operated upon by this process, it was possible to extract sequestra, to scrape the bone, and to cauterize fungosities. Cure followed in every case save one. Hemorrhage, somewhat abundant in a single case, was never sufficient to cause anxiety or to give occasion for the use of ligatures or hæmostatics.—*La Trib. Méd.*, July 19, 1874. A. V. H.

ERUPTION FROM THE BROMIDE OF POTASSIUM (Dr. J. Schwarz, *Wiener Med. Presse*, 1874, No. 37).—Owing to the well-established value of the bromide of potassium in diminishing the activity of the brain and spinal

cord, and more especially in lessening reflex irritability, it is widely administered. It is ordered with especial preference in a large majority of nervous diseases, whether they are accompanied by disturbance of motor or sensory function. When visible results are to be attained from its use, its administration must, of course, be kept up in considerable doses during a protracted length of time. The continuance of large doses is advised against by those who are authorities in such matters, for they say it may be followed by unpleasant symptoms both in the nervous system and on the cutaneous surface. The recorded observations of symptoms coming under the latter head are much more numerous than those which belong under the former.

A. Voison, in 1868, published his observations, and called the attention of physicians to the changes upon the skin which followed the use of the bromide. S. Weir Mitchell followed him in 1870, and in 1873-4 Isidor Neuman added his observations, and Dr. Schwarz wishes to enrich the literature of the subject by the following reports of two cases:

1. A woman, aged about 56 years, had suffered, according to her own account, for many years from attacks of vertigo, which were accompanied by severe cephalic pains, which, starting from the occipital region, extended over the vertex to the forehead. These not alone deprived the patient of her rest at night, but also rendered her days miserable. She stated that she had derived some temporary alleviation from quinine and caffeine, but no permanent good results had been attained by these means. When she was examined in March of this year, she was found to be a well-nourished person, with pretty strongly developed bones and muscles. The heart-murmurs were normal, and nothing abnormal was perceptible in the organs of respiration.

The pulse was 100, the temperature of the skin above 38.5. The patient complained of pain in the head and in all her limbs, which were periodically attacked by an involuntary trembling, followed by chattering of the teeth. As, according to her account, there was a periodicity about these attacks, one-half scruple of quinine was administered during the interval.

These attacks ended with a deep inspiration, and immediately afterwards the patient manifested great sensibility to light and sound, and hyperæsthesia of the skin. The tongue, when protruded, went somewhat towards the left, and the speech, which was at first somewhat indistinct, became regular again after some minutes. The patient was ordered, in conjunction with hydropathic treatment, the bromide of potassium, one drachm a day. After six days of this treatment the epileptiform attacks became less frequent, so that two or three, and even fourteen, days passed without the occurrence of a paroxysm; and, although the treatment was continued, the visits of the physician were discontinued. In the fifth week of the treatment Dr. S. was called to the patient on account of a cutaneous eruption which had made its appearance. The exanthema manifested itself on the forehead in the form of tubercles of the size of a lentil; tubercles of the same character, but larger, were also seen upon the fore-arm and leg. These were found to be hard, and of a conical shape, and surrounded by an infiltrated wall. The eruption was of a pale-red color, and caused an annoying itching. Cool lotions alleviated this symptom to some extent, and, as the paroxysms no longer occurred, the administration of the bromide was suspended. In the course of sixteen or eighteen days the eruption had undergone a retrograde metamorphosis, which began in the lesser and extended to the larger tubercles. On the places where these latter had been seated were blotches of a faint yellow color.

The largest conical tubercle, which was situated on the outer aspect of the left fore-arm, at the end of four

weeks had not been entirely absorbed. The epileptiform attacks began again, but with less severity, and the administration of the bromide in doses of one-half drachm per diem was resumed.

After eight days of this treatment, the large tubercle referred to above began to enlarge, and on the twelfth day from the commencement of this second course of the drug the eruption reappeared. The large tubercle occasioned pain, the smaller ones gave rise only to itching. The use of the bromide was again suspended; and as the general condition of the patient was much improved, she was sent to a thermal spring. W. A.

(To be continued.)

TORTICOLLIS AND MUSCULAR PATHOLOGY.—According to Dr. Dalby, who read a paper on this subject at the recent meeting of the Association Française (*Gaz. Méd.*, September 26), true muscular contraction is due to a lesion of the nervous centres, determining a permanent retraction in which the muscular fibre becomes atrophied and subject to fatty degeneration.

Other forms of contraction which are only apparent consist in a faulty position maintained on account of pain. Under anaesthesia, these false contractions whose effect is thinning and atrophy of the muscle disappear entirely.

Torticollis is often articular, the lesion being seated in the articulations of the cervical vertebrae, particularly that of the atlas and axis with the occipital bone. In torticollis of articular origin tenotomy is useless. The treatment should consist in manipulation, and particularly in the application of hydrotherapy and electricity, but not of induced electricity. A. V. H.

HYPERTROPHY OF THE EAR AFTER EXCISION OF A PIECE OF THE SYMPATHETIC NERVE IN THE NECK (Dr. Bidder, *Centralblatt für Chirurgie*, 1874, No. 7).—One month after resection of the left sympathetic nerve in the neck of a gray, half-grown rabbit, the ear of the same side became much longer and broader than its fellow, and was at the same time hyperæmic and warmer. The left pupil was half the size of the right, projected much farther from the orbit. Bidder thinks that the increased growth of the ear is due to an increase of the quantity of nutritive material supplied to the parts whence the controlling influence of the sympathetic nerve has been removed. W. A.

THERAPEUTIC NOTES.

INFLUENCE OF SUBCUTANEOUS INJECTIONS OF MURIATE OF MORPHIA IN DYSPNOEA.—1. Injections of muriate of morphia seem to possess a real efficiency in all those cases where dyspnoea constitutes an element of the disease or supervenes as a complication.

2. Diminution of the number of inspirations under the influence of the morphia explains the constancy of the results obtained.

3. The effect produced is also more sure and rapid when injection is made into the thoracic walls.—Dr. A. Renault, in *La Trib. Méd.*, Aug. 16, from *Union Méd.*

ADMINISTRATION OF IPECACUANHA BY INJECTION.—Dr. Cheuppe (*La Trib. Méd.*, Aug. 16, from *Bull. de Thérap.*) claims very satisfactory results from this method of treatment in tuberculous diarrhoea and cholera infantum. By the use of this remedy gastric complications are avoided, while the injections may be continued during long periods without disturbing digestion or enfeebling the patient. Under these circumstances ipecac seems to act by absorption.

TREATMENT OF PRURITUS VULVÆ.—Lotions containing alum may be used according to the following formula:

℞ Aluminis, ʒi;
Decoct. hordei, Oiv.—M.

Apply three or four times a day.

M. Hardy employs the following formula:

℞ Hydrarg. bichlor., gr. xv;
Aquæ destillat., ʒiii ʒv;
Alcoholis, q. s.—M.

Sig.—A tablespoonful in a tumbler of tepid water. In applying, care should be taken not to rub the parts.

In that form of pruritus vulvæ which so often accompanies pregnancy, Dangan employs the following formula:

℞ Zinci oxid., ʒi;
Sodii borat., ʒii;
Cerat. simpl., ʒiv;
Ol. amygdal. dulc., q. s.;
Morphiæ muriat., gr. i.—M.

M. Bazin prescribes in pruritus the following liniment:

℞ Liq. calcis,
Glycerinæ, āā ʒviiss;
Ol. amygdal. dulc., ʒi ʒvi;
Ol. rosmarini vel gaultheriæ, gtt. v.—M.

He also occasionally makes use of the following formula:

℞ Glycerinæ, 150 grammes;
Tinct. opii, 4 grammes;
Ol. rosmarini vel gaultheriæ, gtt. v.
—*L'Abeille Méd.*

EXTERNAL TREATMENT OF URTICARIA.—The following applications are used by Dr. Hardy at the Hôpital Saint-Louis, in connection with appropriate internal remedies:

Lotion of Chloroform—

℞ Chloroformi, ʒiiss;
Alcohol., ʒiiss.—M.

Lotion of Corrosive Sublimate—

℞ Hydrarg. bichlor., gr. iss ad iii;
Aq. destillat., ʒiii ʒv;
Camphoræ, q. s.—M.

Sometimes starch-powder, alone or in the following combination:

℞ Amyli, ʒx;
Zinci oxid., ʒss;
Camphoræ, ʒss.—M.

Apply morning and evening. Vichy water, alkalies, etc., may be serviceable at the same time to correct acidity of the stomach.

IN HABITUAL CONSTIPATION.—

℞ Resin. podophyll., gr. ii;
Ext. hyoscyami,
Sapo. castil., āā gr. viii.—M.

Div. in pil. No. xxiv.

Sig.—One at night.

This formula is recommended by Dr. Marchant as a convenient one to avoid the griping sometimes caused by podophyllin, and to exercise a beneficial effect on the condition of the bowels leading to constipation.

CATARRH SNUFF.—Dr. E. C. Mann, of New York, recommends the use of a snuff composed of equal parts of finely pulverized camphor and white powdered sugar as an adjuvant to the various injections and sprays employed in the treatment of nasal catarrh.—*New York Medical Journal.*

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, OCTOBER 31, 1874.

EDITORIAL.

THE PATHOLOGICAL SOCIETY.

THERE lies on the table before us a very substantial evidence of Philadelphia medical earnestness, in the form of a handsome volume of about two hundred and fifty pages, entitled "The Transactions of the Pathological Society of Philadelphia." The book represents a very large amount of good work, and is a valuable contribution to medical literature. The labor that has been given by the "Committee upon Morbid Growths" is very great, and when its voluntary character is remembered, and the fact borne in mind that it can bring but little direct reward to the members of the committee, save the satisfaction of a good conscience, we can well afford to the laborers the praise they so highly deserve. Our Society is the only one of the kind on this continent which publishes a "Transactions;" and, in concluding this notice, we express a desire that it shall not cease from its labors, but that every fall shall bring with it to our editorial table a volume even larger and richer than the present.

CINCHONA CULTIVATION.

WE desire to call the attention of the Committee of the American Medical Association upon the above subject to the *Cinchona Crispa*, which ought to be capable of cultivation on some of our Southern Alleghanies if the account of it published in the *Overland Ceylon Observer* be cor-

rect. It is stated that it resists frost very well, and that, in fact, Mr. Cross found it growing on the summits of the highest mountains around Loja, where the temperature occasionally falls to 27°.

A SUBSTITUTE FOR STEAM.

UNDER the name of carbolem, Dr. Beins, of Groningen, describes in the *Isis*, a Dutch journal, a new invention, which he claims is superior to steam for many motor purposes. He has found that when a bicarbonate of sodium or potassium is heated, dry or in solution, in a closed flask, it yields up a portion of its carbonic acid, which condenses in a cool chamber, so that liquid carbonic acid (carbolem) can be distilled out of those substances at a temperature of from 300° to 400° C. He proposes the use of the liquid for many purposes, such as various stationary and locomotive engines, formation of electric light, etc., etc.; claiming that it is both safer and much cheaper than steam. As an engine with a store of carbolem is independent of the atmosphere, the invention is especially applicable to submarine work, and we believe that the Dutch government is investigating the practical use of the liquid in this direction. Freezing-machines worked by carbolem are said to produce ice much more cheaply than does any method hitherto invented. If this be so, artificial ice must in the course of a few years largely replace the natural product; and if the doctor's calculations be correct, gas will be largely superseded by mechanical electric lights.

As an instance of the excessive fear of blood-letting which affects the profession at the present time, Dr. Rawdon Macnamara gives, in the *London Lancet*, the following incident:

"Some time ago I had a patient under my care suffering under urgent symptoms of impending suffocation consequent upon acute inflammation of the upper portion of the larynx and adjacent parts. A consultation was held of surgeons of great operative ability and also of great experience. All were willing to sanction my opening the trachea, but not one would sanction my opening a vein at the bend of the elbow. However, not being as thoroughly impressed as perhaps I should have been with the importance of the doctrine of the change of type in diseases, I insisted upon bleeding my patient; and never shall I forget his sense of relief as ounce after ounce escaped into the cup, until at last he exclaimed, 'Thank God, I can breathe now as well as ever I did;' and from that out, his convalescence was uninterrupted."

We think Dr. Macnamara is right in suspecting that there are many surgeons who have performed every brilliant feat in the wide range of surgery, but who have yet shrunk from doing the simple operation of venesection. In a very wide experience during the last fifteen years in the hospitals of this city, we have known of but three cases of bleeding,—two having been under our own care.

CREMATION.—It is stated that the municipal authorities of Berlin have recently performed cremation with perfect success, and at a very trifling cost, by the use of gas. In half an hour the softer part of the body had almost entirely disappeared, and in another half-hour the bones had been almost wholly consumed. The skull was then in fragments, and scarcely any part of the remains indicated that they had helped to form a human body.

Dr. Reclam read, at the recent International Sanitary Congress, a paper upon the use of the process after great battles, describing a new apparatus, by means of which a horse can be completely consumed in two hours at an expense of about one dollar. He stated that by his method the horses and men left dead at Gravelotte might have been reduced in four days to a heap of white ashes.

We judge that there are about six hundred medical students in this city. It would be a great blessing if the smaller schools generally were deserted and the only doors of entrance to the profession were the larger institutions. Centralization is a necessity in medical education, if the non-practical chairs are to be properly filled. In it, to our vision, is the only chance of our having in this country professional, not amateur, physiologists, medical chemists, etc.,—men who distinctively devote their lives to such work.

THE clinics at the Philadelphia Hospital are very largely attended this winter. We counted three hundred and twenty-five students at a recent lecture.

REVIEWS AND BOOK NOTICES.

GERMAN UNIVERSITY LIFE. By HEINRICH STEFFENS. Translated by WILLIAM L. GAGE. J. B. Lippincott & Co., 1874.

We lay down this little book at the conclusion of its reading, feeling warm indebtedness towards both author and translator for what is so like a personal introduction to many noble, manly, and world-famous people. Whoever knows of Fichte and Schelling, of the Schlegels, of Schleiermacher, of Goethe, and of that class of grand German thinkers whose influence is felt so markedly by our age, will enjoy a peculiar satisfaction in being brought into such direct relation with the everyday life of the scholars.

A marked charm of the volume lies in the almost boy-like simplicity with which its story is told: indeed, it will be to wonder at if many a reader shall not be found disposed to congratulate himself that he is of greater worldly acumen than Steffens,—pitying, perhaps, the Herr Professor.

"German University Life" is a volume that will interest more particularly the scholar. There is not one paragraph in the whole book which makes entertainment for the reader who would turn its pages seeking for adventures in the bier-garden. The associations lie exclusively with that class whose search is after knowledge of die Bestimmung des Menschen. We quote a single passage; it is the key-note of the work: "Praise and blame are both equally harmless. Whoever has a work to do which absorbs the energies of his whole being, is spending his happiest days. He can build on in peace, and cherish the thought that he is doing a work which shall not perish; if his work is to him something sacred and precious, he can not only bear attacks with indifference, but can even be patient with his weaknesses, while he seeks to battle with and overcome them."

We commend "University Life" as a book to be enjoyed when the evening fires are lighted. J. E. G.

THE TONER LECTURES.—Lecture III. ON STRAIN AND OVER-ACTION OF THE HEART. By J. M. DA COSTA, Professor of the Practice of Medicine in Jefferson Medical College, Philadelphia.

This lecture of Prof. Da Costa is an interesting, well-written, and, we may add, in many respects original brochure, showing that very many cases of heart-disease are in no wise due to rheumatism, or even to endocarditis, but are developed as the results of functional excitement and over-use. It is well known that various occupations predispose to cardiac disease, but excessive dancing as productive of heart-affections has not, that we are aware of, been previously dwelt upon. Baseball players the doctor has found singularly free from heart-trouble, and he believes that the constantly recurring intervals of rest in the game especially protect its votaries.

SELECTIONS.

BENEDIKT ON THE ANATOMICAL CHANGES IN HYDROPHOBIA CANINA.

THE long-continued epidemic of last winter has, through the assistance of his colleagues of the Imperial Veterinary School in Vienna, furnished Dr. Benedikt (*Wiener Mediz. Presse*, June, 1874) with numerous preparations from the brain and spinal cord of different animals that had been attacked with rabies. Before describing these, the author discusses the difference presented by the disease as seen in man and in dogs, which has also a special significance with reference to the anatomical appearances. In both the disease begins with a restless melancholia. In the dog this passes into raving madness, while in man this form of mental affection is wanting. In man illusions and hallucinations take but small share in the symptoms, while in dogs they are plainly a prominent feature. In man there is the greatest degree of hyperæsthesia, with highest possible susceptibility for convulsions; in dogs, diffused paralysis and aphonia are among the earliest and characteristic symptoms. In the human being there is the most extreme reflex excitability in the movements of deglutition, so that not only the raising a glass to the mouth, but even the sight of fluids, will induce violent spasmodic action in those organs; whereas in dogs there is a paralysis of deglutition for fluids. In man the severest spasms of

the respiratory muscles are present, so severe as sometimes to cause asphyxia. Such spasms are not observed in dogs, which die generally from exhaustion.

Dr. Benedikt has studied the pathological changes by making seven separate vertical sections through the hemispheres in dogs, and has observed such plain and striking pathological changes as could, he observes, only have been previously overlooked by reason of an imperfection of the methods of investigation.

In the first place, there is noted an abnormal distention of the meningeal vessels, and the accumulation around them, and in the meshes of the pia mater, of inflammation-corpuscles, together with a nucleolated exudation. This exudation is strongly refractive of light, is colorless, and under high magnifying powers is seen to consist of punctiform nuclear substance (granular disintegration). Striking changes are observed in the gray matter of the convolutions, and in various parts of the nervous centres. One of the coarser changes observed was the presence of numerous holes, or spaces, which, when magnified eighty or ninety diameters, were seen to be filled with a material which also refracted light. This mass, under the high powers of the microscope, consisted of a granular or nuclear substance, in which were single hyaloid and colorless corpuscles, of the size of a distended nucleus of a blood-corpuscle. Inflammatory corpuscles were to be seen in both these masses. In the larger spaces, nerve-cells also were found. Dr. Benedikt further describes what he calls a peculiar condition of the hardened brain, especially in the finer sections. The slightest pressure forced out upon the surface shining masses, which under the microscope proved to be myelin (colloid? *Rept.*). These masses were often found lying detached on the surface of the section, and presented a greenish lustre. The author states that he has seen the same in the spinal cord of a horse that had suffered from rheumatic tetanus, and that he had regarded it as a softening and chemical alteration of the substance of the spinal cord.

The signs of inflammation are not presented everywhere in the pia mater, but only in certain parts. The distribution of these in the gray matter and in the central white substance throws a new light, according to Dr. Benedikt, upon the nature of the "granular disintegration." (A diagram intended to illustrate this point is given.) From what he has noted, it is concluded that the pathological process in this disease consists in acute exudative inflammation, with hyaloid degeneration, which doubtless arises from the exudative infiltration of the connective tissue. It is characteristic with reference to these inflammatory products that the attack, in man at least, is ushered in with rigors. The hyperæmia and nuclear proliferation is concurrent with that form of diffused inflammation which Lockhart Clarke has designated as "granular disintegration," and so far, the author considers, the anatomical obscurity of this disease is dispelled. The morbid process, in man, is doubtless essentially the same. The usual post-mortem appearance is congestion and softening, which may have no especial value except as following asphyxia.

Dr. Benedikt states that there are in literature only two trustworthy reports,—viz., by Meynert, who found much the same appearances as the author. The spaces or holes are regarded by Meynert as being the result of the hardening of the brain-substance. In two other cases Meynert found hypertrophy of the connective tissue in the posterior columns, with molecular and amyloid degeneration in the anterior columns. The nerve-cells of the cortical matter had also undergone partly molecular and partly sclerotic change.

W. B. KESTIVEN.

BOURNEVILLE ON THE THERAPEUTIC AND PHYSIOLOGICAL PROPERTIES OF BROMIDE OF CAMPHOR.

BROMIDE of camphor, or, to use the nomenclature of MM. Maisch and W. A. Hammond, monobromide of camphor (*camphre monobromé* of M. Wurtz), is a substance in which an equivalent of the hydrogen of camphor is replaced by an equivalent of bromine. This new combination is thus very rich in bromine, since it contains of this element more than a third of its whole weight. It is a perfectly definite substance, and, when well prepared and pure, it is white, of velvety appearance, and crystallizes in elongated prisms, which are sometimes of a good size. These prismatic needles are often united at their bases, and thus form thick tufts of great beauty. The odor of the bromide of camphor is rather penetrating, and resembles that of camphor and mouldy wood in conjunction.

The first researches on the physiological action of bromide of camphor were made by Dr. Bourneville, and were communicated by him to the Société de Biologie on June 13. This investigator experimented on guinea-pigs, rabbits, and cats. The results of his experiments induced him to assign the following physiological properties to this new drug. Bromide of camphor lessens the number of the pulsations of the heart, and determines a contraction of the auricular vessels in guinea-pigs and cats; it diminishes the number of inspirations, and lowers the temperature in a regular manner. When the bromine is given in a poisonous dose, this diminution of temperature becomes more and more marked until death ensues. In the cases which recover, the diminution of temperature is succeeded by an increase, which continues until the initial figure is reached. The rise of the temperature, however, occupies longer time than its fall. Bromide of camphor has incontestable hypnotic properties, and appears to act chiefly on the cerebral system. The nervous system appears not to accommodate itself to the influence of this drug, since a prolonged use of it, in the case of cats and guinea-pigs, caused emaciation.

Starting from these physiological conclusions, the results of his experiments, M. Bourneville deduces from them the therapeutic properties of bromide of camphor. He considers that the use of this agent is indicated whenever it is necessary to produce decided calming of the circulation, and especially for the cerebro-spinal nervous system. The antispasmodic properties of bromide of camphor are, in M. Bourneville's opinion, clearly proved. M. Deneffe, of Ghent, is, we believe, the first person who employed bromide of camphor as a therapeutic agent. He found it of great service in the case of a man aged thirty, who was suffering from delirium tremens, accompanied by tremblings, excitability, insomnia, and visual delusions. The patient improved rapidly, and a thorough recovery followed, unattended by relapse.

Dr. W. A. Hammond, of New York, employed bromide of camphor prepared by M. Maisch, Professor at the College of Pharmacy in Philadelphia, in the form of beautiful free crystals slightly tinted with yellow. Dr. Hammond mentions instances where the convulsions of children, attacks of inveterate hysteria, lasting from five to twelve days, and headache, consequent on mental excitement or excessive study, were cured by the use of this drug.

Dr. Bourneville made his therapeutical experiment at the Salpêtrière, under the direction of M. Charcot. The form of the drug administered was the same as that which has been employed up to the present time in all the hospitals of Paris,—Dr. Clin's bromide of camphor dragées. In addition to the physical properties of bromide of camphor already mentioned, its

characteristic odor and disagreeable flavor, it may be noted that it is insoluble in water, and changes when exposed to the air, so that the dragées are the best form in which to administer it. Each dragée contains exactly ten centigrammes ($1\frac{1}{2}$ grains) of the bromide of camphor, covered by a thin coat of sugar, which preserves the drug, masks both its odor and flavor, and renders it easy of deglutition. These dragées become rapidly disintegrated in the stomach. Among the cases already published we find the following:

In one case, a woman aged sixty-two, suffering from heart-disease attended by insomnia, twenty centigrammes only (two dragées) were efficacious. In the case of a woman aged forty-six, who was suffering from progressive locomotor ataxy, in whom insomnia alternated with disturbed sleep, troubled by nightmares, it was necessary, in order to obtain a decided improvement, to administer eighty centigrammes (eight dragées). A woman aged forty-six, who for six years suffered from chorea, who had not been able to walk for a year, and was tormented by such incessant and violent movements that they threw her out of her bed, and who was also unable to sleep, had administered to her as high a quantity as one hundred and twenty centigrammes (twelve dragées). Her sleep became calmer, she remained quietly in her bed, could walk a little, and often remained fifteen or twenty minutes undisturbed by choreic movements.

Three women under the care of M. Charcot, of the respective ages of fifty, sixty, and sixty-seven, were attacked by paralysis agitans, and pronounced incurable. They took from twenty centigrammes to one gramme (three to fifteen grains) of the bromide of camphor, daily, in quantities varying from one to ten dragées, in progressive doses. A marked amendment followed.

Bourneville (*Progrès Médical*) has submitted the efficacy of bromide of camphor to a severe test by choosing as a field for his experiments a hospital for incurables. If it succeeded in these obstinate cases, still greater was the probability that it would act beneficially where the conditions were more favorable and the illness of more recent origin. A patient in the Hôpital de la Pitié, twenty-four years of age, suffering from acute rheumatism, was attacked by chorea in the left arm. He was cured in five days. The dose was sixty centigrammes (nine grains) daily, given in six dragées.

In the same hospital, a woman aged twenty-two was attacked by violent hysterical chorea, with hysterical vomiting. The dose given was first forty, and then sixty, centigrammes daily. Her cure was rapid.

A young woman, a patient in the Necker Hospital, suffering from induration with insufficiency of the mitral valve, showed symptoms of poisoning from the first day digitaline was administered to her. The digitaline was discontinued, and the bromide of camphor substituted. The heart-beats diminished in frequency and became regular. The medicine was relinquished, and the improvement obtained continued the same a fortnight later.

A man in the same hospital, presenting the same conditions, received equal relief.

A young woman, suffering from nocturnal incontinence of urine, had taken bromide of potassium during fifteen days without any amendment. Four dragées of the bromide of camphor cured this painful infirmity, at least for the time being. The patient is still under treatment.

A patient who was tormented by nervous cough, which entirely deprived her of sleep, took two dragées, night and morning, and the symptoms were abated in a few days.

At the Cochin Hospital a case of paralysis agitans

was considerably calmed by a daily dose of four dragées. The patient was a woman, about forty years of age.

At the present time our knowledge of the physiological action of the bromide of camphor, and of its value as a therapeutic agent, is imperfect. It is, nevertheless, evident that the administration of this drug has been followed by incontestably beneficial results, which have been corroborated by observation in a number of the hospital wards. Bromide of camphor is a well-defined substance, having a characteristic crystallization, smell, and flavor; and a powerful sedative both to the nervous system and circulation, acting as a hypnotic and regulating innervation.

It would be premature to specify the precise dose which ought to be administered. In the generality of ordinary cases it has been given to adults in doses of from twenty centigrammes to one gramme, a dose two or three times during the morning, a dose before dinner or with it, and, finally, another before going to bed. The dose naturally varies according to the illness and the special symptoms presented.

E. LAWSON.

—*London Medical Record.*

GLEANINGS FROM OUR EXCHANGES.

WOUND OF NECK AND LARYNX—RECOVERY (*Edinburgh Medical Journal*, September, 1874).—Dr. Joseph Bell reports the case of a man who had received a fearful wound of the neck by the accidental falling of a scythe. The cut extended nearly from ear to ear, was nine inches in length, and, passing through the larynx, divided the thyroid cartilage in the most complete manner, so that not only were the two halves separated in the middle line, but each half was cut transversely across by a ragged wound; a flap with inverted edge and its convexity upwards consisted of skin and platysma; the sterno-mastoids were notched at their edges; the sterno-hyoids were both divided transversely; the great vessels and the oesophagus had escaped. All the bleeding points were at once tied, and then tracheotomy was performed, and a tube inserted in the usual place. This not only gave access of air, but also acted as a drain to the flap, which had been so cut as to retain all discharges. The severed portions of the thyroid cartilage were then brought into accurate apposition with catgut sutures, which were all passed in the different directions before any of them were tied. The whole of the rest of the wound was then closed, and the patient was placed in a large, airy room, with a good fire and plenty of steam. In three days the bulk of the wound was healed, but once or twice he had bled rather freely from the tube; the blood, which was recent, seeming to come from the mucous membrane of the larynx itself. There were also here and there, in both lungs, crepitant râles, due, doubtless, to the presence of clotted blood, and perhaps to the breaking up of clots of blood in the lesser bronchi. There was a little frothy grumous discharge from the tube. He was ordered turpentine stupes to his back, and to be well fed with milk and beef-tea. In two weeks the tube was removed, and two weeks later the whole wound was healed, the tracheotomy wound was almost entirely closed, and his voice was a little hoarse, but was improving daily.

SLIGHT INJURY TO LEG, FOLLOWED BY SUDDEN DEATH FROM THROMBOSIS (*The Lancet*, September 19, 1874).—Mr. A. B. Shepard reports the case of a healthy man, æt. 49, who accidentally abraded his left shin, the wound on which almost entirely healed under

ordinary treatment. On the twenty-first day after the accident, he fainted and fell. Three days later, he had a rigor, followed by well-marked signs of simple pleurisy on the right side. Six days later he fell down while dressing, and died.

The autopsy was made forty-eight hours after death. There was most extensive decomposition of the head, neck, and upper extremities, the superficial veins being much discolored. There was no great decomposition of the body externally below the level of the diaphragm. All the organs were healthy, but very much decomposed. The blood throughout the body, with the exceptions noticed below, was fluid. Coiled up in the apex of the right ventricle were three moulded clots, one showing most beautifully the impression of vein-valves. Two of these clots exceeded seven and one-fourth inches in length each. Only one very small clot, soft and recent, was found in a branch of the pulmonary artery. The subclavian, jugular, iliac, and femoral veins, and the vena cava, were carefully examined. The left internal saphena was removed from two inches below the original wound to its entrance into the femoral, and the latter itself to below the popliteal vein. On slitting up the saphena, the coats of the vein below the region of the wound were found to be perfectly normal, semi-transparent, and drying rapidly on exposure to the air. Nearer the wound its coats cut more rottenly, and where the smaller veins from the wound entered it, it was dilated. From this point upwards, its internal coat, as well as that of the veins from the wound and of those dipping down to the deeper vessels, was intensely red, more than blood-stained, swollen, and moist, even after long exposure to the air. The same was the case with the femoral and popliteal veins; the coats of the latter were greatly swollen, and injected a dark, black-currant color; and in the popliteal vein itself lay the debris of a clot, non-adherent to the vessel-wall, and extending for more than three inches from above to below a pair of valves, the same, in all probability, which had left their impression on the clot in the right ventricle.

THE FORM OF THE CAVITY OF THE UTERUS.—Hagemann (*Archiv f. Gynaecol.*, Band v.) has made a series of plaster-of-Paris casts of the interior of the uterus, and finds that the form of the uterus in a new-born child is distinctly bicornuate, a crista media being still visible as a remains of it in the virgin at puberty. Women who have had children, and old people, have still some indication of it in a marked prominence of the walls at the point of entry of the Fallopian tubes. In childhood the uterus is very narrow from before backward. In multipara the transverse diameter, just above the orificium internum, is very considerable. On the other hand, in virgins the cervical canal is half the whole length of the uterus. The cervical canal is widest near its centre. The cristæ of the plicæ palmatæ are situated the one in front and to the left, the other behind and to the right. The retrogressive metamorphosis of the uterus after birth does not affect the whole uterus equally, but chiefly the placental region.—*The Lancet*, September 19, 1874.

EFFECTS OF DIVISION OF THE AUDITORY SEMICIRCULAR CANALS.—Dr. Löwenbey gives the results of his experiments on the semicircular canals in Dr. Knapp and Professor Moos's "Archives of Ophthalmology and Otology," vol. iii., 2, p. 26. He believes they prove the following points: 1. That the derangement of motion following division of the semicircular canals is the result of this injury, and not of an accompanying injury to portions of the brain. 2. That the vomiting observed by Professor Czermak in his experiments was the result of an accompanying injury of the cerebellum.

3. That the derangements of motion are the result of irritation of the membranous canals, and not of paralysis. 4. That the irritation of the semicircular canals produces the convulsive movements *reflectively*, without participation of consciousness. Consciousness participates in these effects only in so far as it gives rise to renewed irritation by inciting the animal to voluntary movement. 5. The communication of this reflex excitation from the nerves of the membranous semicircular canals to the motor nerves takes place in the thalamus.—*The Lancet*, September 19, 1874.

MULTIPLE FRACTURES (*The Dublin Journal of Medical Science*, September, 1874).—At a recent meeting of the Dublin Pathological Society, Dr. Bennet presented specimens taken from a man injured by the falling-in of the roof of a house, and who had sustained the following injuries. A transverse fracture of the lower third of the right thigh bone; an oblique fracture of the right tibia and fibula; an oblique fracture of the lower end of the right humerus; fracture of the sternum at the level of the junction of the manubrium and gladiolus; fracture of every rib on the right side, and of the first three on the left; extensive rupture of the chest-wall with great emphysema; several wounds of the right lung. He survived the accident for three hours.

CASE OF GASTRO-ELYTROTOMY (*New York Medical Journal*, October, 1874).—Dr. Alexander Skene reports a case of pregnancy in a rachitic patient who had gone to full term. When labor began it was found impossible to deliver the child either by version or craniotomy, on account of the narrowness of the pelvis and the œdema of the parts. Gastro-elytrotomy was performed, and the child extracted with ease. Dr. Skene observes that the incision was made through the skin and superficial fascia from the spine of the pubis to the anterior superior spinous process of the ilium, but that this was longer than necessary. The muscles were divided for about two-thirds this distance, the opening thus made being very distensible. The finger was used to raise the vagina at the point where it was opened. The head was seized with the craniotomy-forceps and delivered. This operation, Dr. Skene thinks, should take the place of Cæsarian section, and should be tried in deformity of the superior strait where the child could be saved.

ACETIC ACID IN MUCOUS POLYPUS (*Ibid.*).—Dr. Méplain, of Moulins, gives the history of a man, thirty years of age, who had been afflicted for a month with mucous polypus of the velum palati. The tumor was growing rapidly, and impeded deglutition and speech, and gave rise to considerable hemorrhage. Applications of chromic and carbolic acids, removals with scissors, etc., afforded no relief, the tumor being constantly reproduced. A drop of acetic acid was injected into the polypus, and it immediately began to shrink; a second injection completed the cure, and five months later there were no symptoms of a return of the disease.—*Bull. de Thérapie et Gazz. Med. Ital. Prov. Venete*, No. 9, 1874.

CASE OF OVARIOTOMY (*The Western Lancet*, September, 1874).—Dr. John Scott reports the case of a patient, æt. 34, from whom a large ovarian tumor was removed. She was at the time greatly emaciated, having symptoms of blood-poisoning. There were extensive parietal and omental adhesions to the tumor, and strong fibrous bands attached it to the liver and spleen. Beyond half an hour's pain in the back immediately after the operation, the patient had no suffering whatever, and progressed steadily to recovery, with no vomiting, tympanites, or derangement of the stomach or bowels. A glass drainage-tube was used. Ethyl was employed as the anæsthetic.

MISCELLANY.

MEDICINE IN SWEDEN.—An interesting article on the recent Archæological Congress at Stockholm, by M. Albert Kobin, published in the *Journal de Thérapeutique* for September 25, gives some details respecting the hospitals and medical schools of Sweden. It appears that in that country there are seventy-nine hospitals, containing 4687 beds, receiving an average of from 30,000 to 32,000 patients, with an annual death-rate of about 2000. The expenses of these hospitals amount to about 40,000*l.* per annum. There are nine lunatic-asylums, containing 1210 beds. In 1870, statistical returns showed 9109 lunatics, of which 4666 were men and 4443 women. There were also 3280 blind persons,—1504 men and 1776 women; 5254 deaf and dumb, comprising 2370 men and 1848 women. Stockholm contains seven hospitals, of which the most important is the Clinical Hospital, containing 300 beds. The wards of this institution are small, low, badly lighted, and in a very indifferent order. It is very difficult to ventilate them: they are therefore about to be replaced by a construction on the pavilion plan. At the head of each bed is a small black tablet, on which the clinical clerk writes his chief's remarks every day. The surgeons have begun to use the wadded splints, but find it difficult to give up the use of Lister's bandages, which they have unanimously adopted. In Norway they employ a method of dressing wounds which was used by the Americans in the war of secession. Lint and wadding are replaced by fine tarred oakum, the bandages and other portions of the dressing being impregnated with acetate of alumina. This method of treatment yields excellent results, and Dr. Thaulow, of Christiania, employs it in his wards to the exclusion of any other. The only specialty to be seen in the medical wards is the plan used for the cure of acute affections of the chest, such as pneumonia and acute bronchitis. It consists in making the patient constantly respire air holding in suspension a large quantity of aqueous vapor; the bed being entirely covered with a moderately thick cloth, in which two apertures are made for the renewal of the air. A water vaporizing-apparatus is placed at the foot of the bed, to the level of which the vapor is conducted by a tube. This method of medication, which, however, is not new, is tolerably successful, especially in children's cases.—*London Medical Record.*

RECENTLY, at lunch, meeting Colonel Gordon and Dr. Bellew, just returned from Yarkand, they mentioned that the cold was twenty-six degrees below zero at 18,500 feet, when bed-clothes were welded together by frozen perspiration, which the heat of the body would not thaw, and, as ink and colors solidified, their notes and sketches had to be pencilled. Excepting the accomplished naturalist Dr. Stolicza, who died of symptoms allied to those of sunstroke, depending on cold and rarefaction of the air, all during the year enjoyed excellent health, whilst living on sheep, green tea, and

occasionally horse-flesh, very little liquor or tobacco being expended.—*Indian Correspondence of the Medical Press and Circular.*

CANNIBALS' TASTES.—In the anthropological section of the recent congress at Lille, reported in the *Revue Scientifique* of Sept. 12, one of the subjects discussed at some length was the practice of anthropophagy. M. Broca thereupon made some remarks on the different nature of the flesh of different races. He said that the cannibals, perhaps fortunately for us, do not like the flesh of whites: they find it bitter and salt, whilst, notwithstanding the latter quality, it does not keep well. Their special dainty is the flesh of the negro, of which they like the flavor, and which becomes dry by keeping rather than decomposes by the natural process.—*London Medical Record.*

OUT-OSTRICHING AN OSTRICH.—In another column we have recorded the case of an American girl who died recently from eating clay. We have now to add another victim to extraordinary taste, in the person of a shoemaker, on whose body an inquest was held on Saturday, at Manchester. The post-mortem showed that the stomach contained one pound ten ounces of nails, several pieces of half-inch square iron, and an awl without a handle. The jury returned a verdict of death from peritonitis, in accordance with the medical evidence.—*Medical Press and Circular.*

THE Professor of Materia Medica and Clinical Medicine in the Calcutta Medical College, Soorgo-Coomar Goodeve Chuckerbutty, M.D. Lond., died on the 29th ult., at Kensington, aged forty-eight.

DR. THOMAS NEWHAM reports (*London Lancet*) a case of death from measles in a man aged ninety-three.

M. CLAUDE BERNARD has been chosen Director of the French Academy.

NOTES AND QUERIES.

ERRATUM.—By a curious oversight, Dr. Goodell's name was not appended to the article upon the Preston Retreat which we recently copied. It matters less, however, as every one knows that Prof. Goodell is the head of the institution.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A CONVERSATIONAL meeting of the Philadelphia County Medical Society will be held Wednesday, October 28, at 8 o'clock P.M.

Dr. James Collins will read the opening paper.

All regular practitioners in the city are invited.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM OCTOBER 20 TO OCTOBER 26, 1874, INCLUSIVE.

HEAD, J. F., SURGEON and MEDICAL DIRECTOR.—Relieved from duty in Department of Dakota, to proceed to Boston, Massachusetts, and, upon arrival, report by letter to the Surgeon-General. S. O. 229, A. G. O., October 22, 1874.

DE HANNE, J. V., ASSISTANT-SURGEON.—To report in person to the President of the Army Medical Board, New York City, for examination for promotion, and, upon its completion, to the Commanding General, Military Division of the Atlantic, for assignment to duty. S. O. 229, c. s., A. G. O.

SATURDAY, NOVEMBER 7, 1874.

ORIGINAL COMMUNICATIONS.

OBSERVATIONS ON THE HYPODERMIC USE OF ATROPIA IN MUSCULAR RIGIDITIES, RHEUMATIC AND MYALGIC.

BY J. C. WILSON, M.D.

OF the following cases, one was furnished by the Medical Ward of the Pennsylvania Hospital, where, thanks to the kindness of the attending physician, I had the opportunity of observing the patient and making clinical notes of his condition and treatment. The remainder presented themselves during the past year at the medical clinic of the Jefferson Medical College. I venture to give them to the readers of the *Philadelphia Medical Times* at some length, as they illustrate a disease sufficiently common in this climate, especially among the so-called laboring classes, but which, nevertheless, has not received the attention from writers upon medicine which its frequency and the suffering it occasions demand, and because they at the same time demonstrate most satisfactorily the efficacy of the method of treatment first suggested by Da Costa in the first volume of the Pennsylvania Hospital Reports in 1868, in an article "On Certain Forms of Muscular Rheumatism, particularly Wry-neck and its Treatment."

The disease is that painful muscular rigidity known as chronic muscular rheumatism or chronic myalgia in all its forms; the treatment is the hypodermic use of atropia.

Case I.—G. R., aged 17, born in Germany, by trade a shoemaker, had, in April, 1873, an attack of acute articular rheumatism, in which the joints of the upper extremities were affected, and more severely those of the right side. The attack was of mild type; it lasted some five or six weeks. No discernible cardiac lesion resulted. As the articular pains subsided, the cervical muscles began to give trouble. The neck, first on the right side, then on the left, became painful, stiff; the muscles were hard. Motion was limited, and attended by an increase of the pain. Gradually the head was drawn to the left side. The pain, varying in intensity, but constantly present, aggravated by movements, by pressure, and by atmospheric changes, prevented him from work.

On admission to the Pennsylvania Hospital, November 21, 1873, his condition was as follows: Head drawn strongly to the left side, and slightly backwards, the chin being rotated to the left so that it almost rests upon the clavicle. Left shoulder elevated. Pain constant, dull in kind, referred to both sterno-cleido-mastoid muscles, but severer on the left side, where it extends to brow. Movements of all kinds aggravate it. The muscles, both the sterno-cleido-mastoid and the trapezius of the left side, are hard and tender to even slight pressure. The patient is pale; his expression is indicative of suffering. There is no joint-trouble. Appetite fair. Was ordered atropia, gr. $\frac{1}{60}$, by hypodermic injection, over the affected muscles daily.

December 4.—The following note was made: Pain almost gone. Can move the head freely in all directions; carries it stiffly, and a little to the left. There is

still a trifling pain over the upper part of the left sterno-cleido-mastoid muscle, where a little hardness also lingers. The muscles elsewhere feel normal in texture.

The treatment was continued as an occasional injection of atropia, with the addition of ferruginous tonics, the recovery being at this time almost complete.

December 24.—The patient was discharged, cured.

Case II.—J. S. C., aged 65, applied for treatment October 16, 1873. He is a stone-mason, and has been greatly exposed to the weather all his life. States that he had an attack of rheumatism twenty years ago, which affected his legs, and laid him up the greater part of a winter, but thinks he had no swelling of the joints. Since that time has had occasional twinges of pain, and some stiffness of back and legs after working in bad weather. The present trouble began a year ago, with pain in the back of his head. This pain extended into the muscles of the neck, and now extends, he says, down into his throat. The pain is always present, and is aggravated by efforts at motion and by pressure, so that he carries his head very erect, even a little backwards, and to the left. The left shoulder is elevated; the sterno-cleido-mastoid muscle and the trapezius of that side rigid. Cannot turn head to the left, but can to right. Stooping is very painful. The pain is worse at night. Is anæmic, anxious-looking. Has no disease of the heart. No family predisposition to rheumatism. Was ordered extract of belladonna in small doses, repeated till pupils were affected, with quinine and liniments.

After one week of this treatment, no benefit resulted.

October 23.—Atropia, gr. $\frac{1}{60}$, daily, hypodermically, in region of affected muscles.

About half an hour after insertion of the drug he always felt a little dull and confused, and had the usual dryness of throat and dilatation of pupils, with later diarrhœa. In no instance anything like redness of skin. During the treatment he did not have to rise at night to void his water according to habit.

There was decided relief of suffering directly after the first injection.

After eight injections the daily use was abandoned, and only one or two more were made at longer intervals.

November 4.—This note was made: Carries head erect; is free from pain; can turn head as much to the left as to the right, with a little effort. A crackling sound is heard when head is suddenly turned to left side; and there is still some hardness of the muscle of left side. Stoops with ease. Sleeps well. Ordered elixir iron, quinine, and strychnine, f3i t. d.

These two cases show, the first, a close and evident, the second, a remote and vague, association with attacks of articular rheumatism. Whether this relation is causative or merely accidental is a question not so readily determined as might at first sight be supposed.

The results of extended clinical inquiries fail to establish the dependence of such cases upon the causes that produce articular rheumatism, or that they occur more frequently in those who are of the rheumatic diathesis than in others. Indeed, as the following case shows, an acute attack of sickness of a wholly different kind may be followed by painful rigidity in a group of muscles prone to it.

Case III.—A. C., a German, aged 17, a tailor by trade, applied December 29, 1873, on account of stiffness and pain in his neck. The trouble began in September, after a "severe cold and inflammation of his throat." It has gradually increased till this time. The throat-trouble, which would appear to have been a transient tonsillitis, has disappeared. His condition is as follows: Constant

but not severe pain, aggravated by every movement, on the left side of the neck. Can rotate head to the right, not at all to the left; efforts to do so occasion very severe pain. Carries head stiffly, and tilted to the left. A little general denseness of muscles on left side of neck,—those lying between the sterno-cleido-mastoid and the anterior border of the trapezius being hardest, that is, the focus of the trouble being in the *scaleni* muscles. Is pale, suffers from acne, and has two or three enlarged lymphatic glands in the post-cervical region.

Treatment.—Atropia, gr. $\frac{1}{60}$, hypodermically, over point of greatest pain. After some minutes the pain was greatly relieved, and motion to a considerable extent restored. Ordered pil. rhei comp., U.S.P., one at bedtime, daily.

The atropia was repeated every third day till January 6, 1874, when (after four injections) he was free from pain; could move his head with ease, carried it in the normal position, and ceased attending. This case was not a severe one; he worked all through it, sewing on his board. The hardness of the muscles vanished under the treatment.

Twice since, at intervals of months, he has had a slight return of the trouble, which a single hypodermic of atropia, gr. $\frac{1}{60}$, has stopped.

Here we have myalgia, of which one of the most important predisposing causes was the depressing influences of sickness. The four cases that follow are myalgia from overwork.

Case IV.—J. K., aged 28, a laborer, applied October 20, 1874. Has had pain and stiffness in the small of his back for two years. This came upon him gradually, and did not prevent his working until a few months ago, although he has for eighteen months had great trouble in lifting heavy loads. At present he cannot bend his back; in essaying to do so, moves his body from the hips at an angle, the back remaining stiff and rigid. When he stoops, he cannot rise without the aid of his hands upon his knees. Gait slow and hesitating, because the slightest jar is painful; and he says that if he stubs his toe he feels as though his back would break. Pain is always present, and increased by all movement.

A careful examination excludes spinal and renal disorders. The erector spinæ mass of muscles on both sides is very rigid, standing out in firm, unyielding columns, which impart to the finger a very different sensation from that of healthy muscles. The left side is a trifle less hard than the right, and on strong effort at bending perhaps relaxes a little.

The man has never had articular rheumatism; has no heart-trouble. He is pale, and has lately lost flesh. He has endured a great variety of treatment, including blistering and hypodermic injections of morphia, but has experienced no relief. Ordered hypodermics of atropia, gr. $\frac{1}{60}$, daily.

October 27.—Has had five injections, some into the subcutaneous tissues, some directly and deeply into the body of the erector spinæ muscles. The effect in relieving pain is the same in each case. He has now but little pain; can stoop and rise, lifting a weight; even bends his back a little. The gain in point of suffering is immense.

Up to November 1, he had in all thirteen injections of the drug, each gr. $\frac{1}{60}$, and ceased attending, reporting himself able to go to work. The muscles were still rigid, especially on the right side, but decidedly less so than when first seen.

Case V.—J. O'H., aged 45, a laborer, came under observation May 10, 1874. He suffers from "lumbago," has great stiffness in back, attended with pain which extends into left hip and across the fore-part of his left leg. It came on suddenly four weeks before, after un-

usually severe muscular exercise, which was, however, only some fifteen or twenty minutes in duration. Being out of work, he chanced to meet a comrade in the street who was employed as a "rammer" in repairing cobble pavements. With a view to seeking work of that kind, he took his friend's place for a while, "to get his hand in." When he stopped he had great pain and soreness, and could scarcely reach home. For several days movements were very painful, and he was compelled to keep his bed. He slowly improved, and got out again, but has been quite unable to work. Has more or less pain in lumbar region, increased by walking, etc. He cannot stoop without great pain, and, if he does so, is unable to rise without assistance. Erector spinæ affected. The left side harder, fuller, more painful than the right. General health good. Has never had articular rheumatism; occasionally has had muscular pains in shoulders, but never severe enough to oblige him to leave off work.

Treatment: atropia, gr. $\frac{1}{60}$, into left erector spinæ mass.

May 11.—Atropia, gr. $\frac{1}{60}$, into left side.

May 12.—Atropia, gr. $\frac{1}{60}$, into right side. Has less pain; can stoop with relative ease.

May 13.—Feels a great deal better. Pain lingers in hip. Can stoop, walk, run, with ease. Except slight dilatation of pupils, has had no signs of general physiological influences of atropia.

May 15.—Had some return of pain yesterday, after improper exertion. Is better to-day; in fact, has no pain. Some rigidity of the muscular pillars of the back persists. Feels able to go to work.

I injected the atropia five times in all, and have not seen him since. There is the best reason to believe that he would have returned if there had been any further trouble.

Case VI.—C. K., aged 68, a retired seaman, applied June 5, 1874. He has never had rheumatism; is not subject to muscular pains; to use his own expression, "has not had a pain of any kind for thirty years," until ten days ago, when, after an unaccustomed strong muscular effort in helping to lift a barrel of rice, he was at once seized with pain in the small of his back. This was not severe when he was quiet, but very bad whenever he attempted to move, so that for more than a week he was scarcely able to turn in bed. The pain extended from the lumbar region into both thighs. Has a good deal of stiffness now, and cannot stoop to tie his shoes; has to have assistance in rising from his chair. Muscles of the back somewhat hard, with a degree of tenderness on pressure. Has had no fever; tongue clean, appetite excellent. Plasters and various liniments have been, he states, of no service.

Injected atropia, gr. $\frac{1}{60}$. Immediate relief.

July 9.—Reported that the morning after his visit he was able for the first time in ten days to tie his shoes. Injection repeated, and so on at intervals of two or three days, until four were given. Some weeks later he called to say that he had had no further trouble and to express his gratitude.

Case VII.—M. N., aged 45, laborer in a rolling-mill, was first seen October 13, 1874. He has very heavy lifting to do, and has had for four years a severe pain and stiffness in his right arm near the shoulder. This trouble is not constant. When he is at work, warm and sweating, he feels "all right," and can use his arm freely; but as soon as he stops and begins to cool off, the pain and stiffness return, and continue until work or exercise again warms him up. The pain is very severe, and movements of the arm evidently give rise to exquisite anguish; it is worse at night, so that sleep is often impossible. On examination, the arm and shoulder are found to be normal in size and outline, but the right deltoid muscle is a trifle firmer in texture

throughout than its fellow of the opposite side, and is tender to the touch. But at the region of its insertion it is exceedingly hard and rigid, feeling like bone.

Has not had rheumatism. General health good. Expression anxious and careworn. Given belladonna, with a liniment.

Oct. 20.—Returned, not relieved by the treatment. Injected atropia, gr. $\frac{1}{60}$, into subcutaneous tissues near insertion of the deltoid muscle. This was followed by tremor of the arm and quivering of muscles. It was done at Professor Da Costa's clinic, in the presence of the class, and the patient was directed to sit outside a few moments. In ten minutes he returned to the lecture-room, swinging his arm around his head, quite free from pain, and happy, saying, "Oh, if it would only last!" The muscle was quite supple and natural in texture at this time, except at its insertion, where there was a slight denseness, trivial in comparison to the previous condition, which almost resembled to the touch an exostosis. Poor fellow! the relief lasted only a few hours. Once afterwards I injected atropia, with a like result, but he became discouraged, and has not returned.

In reviewing these notes, it will be observed that in Case I. there is a clear history, and in Case II. a doubtful history, of articular rheumatism, in Case III. a history of acute tonsillitis, and that the remaining four are cases of pure myalgia. All were males.

The solution employed was of the strength of gr. i ad $\mathfrak{f}\text{v}$, of which $\mathfrak{M}\text{v}$ = gr. $\frac{1}{60}$.

Slight dilatation of the pupils was invariably observed in a few minutes after the injection; very frequently dryness of the fauces, with thirst; occasionally a feeling of confusion and dizziness, which, however, was of short duration. Sometimes diarrhoea was noticed after repeated hypodermics, and the old stone-mason (Case II.) was relieved of his usual necessity of rising at night to void urine, while under treatment. The belladonna eruption was not observed in any of these cases.

With a smaller dose than one-sixtieth of a grain, say one-eightieth or one-hundredth, I have failed to obtain the prompt relief afforded by that dose, and I have found doses larger than one-sixtieth unnecessary.

In Case II. small inflammatory nodules occurred in the integuments at two of the points of injection, but disappeared in a few days without suppurating. Other than this I have seen no local inflammatory action follow hypodermics of solution of atropia.

In these cases relief was not only decided, it was also prompt, and in six of the cases effectual. In Case VII. it is no more than fair to presume that a continuation of the treatment in conjunction with rest would have resulted favorably.

It would be foreign to the purpose of this paper to enter upon the discussion of the essential pathological condition underlying these cases. At some future time I hope to publish a brief summary of the opinions that have obtained in reference to this form of painful disease of the voluntary muscles. At present my object has been to so group a number of cases as to illustrate with definiteness the nature of the trouble under consideration, and to show the effects of a special treatment.

Whether the cause of the common symptoms be rheumatism of the muscles, or hyperæmia, or inflam-

mation with slight serous effusion, or partial paralysis of vaso-motor nerves, with escape of serum into the intimate tissues of the muscles, or a neuralgia of the minute nerve-twigs supplying the muscles, it is certain that the terminal nerves are thrown into a state of irritation which expresses itself in pain and in spasm.

Spasmodic contraction occurs at first, as a rule, only when the muscles are brought into use; later, a condition of tonic spasm, a spastic rigidity, comes on; and, finally, such tissue-changes take place as to lead to great impairment or absolute loss of function with or without atrophy.

In the earliest stages, that is, in the acute form, I have not found atropia beneficial. Hypodermics of morphia, on the other hand, have been serviceable in allaying the pain and inducing repose, but this quite independently of any local action. But later, when the disease has become chronic, or in some cases when it is from the outset of the chronic form and the element of spasm is present with more or less rigidity, atropia used locally is, as the cases show, of prompt and certain benefit. There seems the strongest reason to believe, both from clinical observation and from the researches of experimental physiologists, that the benefit arises from the direct sedative effect of the drug upon the nerve-filaments, and that it thus, by relieving the irritation, relaxing the tonic contractions, and putting an end to pain, enables the circulation and nerve-supply to resume their normal course and relations.

But after a long time, when permanent changes have taken place in the tissues, it is useless to hope that any treatment will restore to the muscles their suppleness and contractility. But even then much may be done by this means in relieving pain, and enabling the patient to avail himself of supplementary and auxiliary muscles in performing customary movements (vide Case IV.). Contrary to the experience of Wood, who states that the drug must be thrown "directly into the muscle" (vide Wood's Therapeutics, p. 222), I have found that the effect is the same whether it be injected directly into the muscle or into the subcutaneous tissue overlying it; and I recall clinical lectures of Dr. Da Costa's, in which he stated that the injection might be made, and that he had repeatedly tested this point, into distant parts of the body, with a result scarcely less decided than when in the immediate vicinity of the rigid and painful muscles.

Let me add that in looking over the literature of this kind of muscular rigidities I have been struck with these points: first, the absence of anything like a direct recognition of the fact that the rigidity is at first spastic; and second, the uncertainty, not to say inutility, of the long list of remedies adduced for the relief of this trouble, which, trivial as it certainly is in point of prognosis as regards life, is to the working-man most serious, since it is extremely common, very painful, and too frequently absolutely unfits the sufferer for long periods of time from earning his livelihood. A recognition of the fact, then, that the rigidity is, in its earliest stages, a form of tonic spasmodic contraction, coupled with our knowledge of the action of atropia upon muscular

spasm, has led to a systematic and thorough trial of this treatment, the notes of which are given to the profession.

SUDDEN DEATH FROM RUPTURE OF A UTERINE CYST (EXTRA-UTERINE PREGNANCY?).

BY A. K. MINICH, M.D.

MRS. K., aged 35, mother of eight children, the youngest a suckling, retired, feeling well. At 11 o'clock, same night, she was seized with violent pain in the lower portion of the abdomen. I saw her for the first time the next morning at 8 o'clock, and found her in a state of collapse. The mind was clear, and her chief complaint was of great pain in the hypogastrium. Her surface was cold, and covered with a clammy sweat; the pulse feeble, ranging from 144 to 160 per minute. The uterus was normal in position. She was ordered quinine and brandy, but died at 3 P.M., sixteen hours after the attack.

The autopsy was made thirty-six hours after death. There were no signs of inflammatory change in the abdomen. A basinful of blood-clots was scooped from the lower portion of the abdomen, with about two-thirds of a bucketful of dark-colored blood. Upon the right side of the fundus of the uterus, corresponding to the junction of the Fallopian tube, was a lacerated opening, which looked into the abdomen. This opening was about the size of a pea, and communicated with an empty sac, which, when distended, would probably have been as large as a hulled walnut. The sac did not communicate with the Fallopian tube or the cavity of the uterus. Its walls were very thin, and free of clots or deposits. The blood-vessel through which her life ebbed so slowly yet surely away was very small, being scarcely perceptible. She had menstruated one week beforehand.

NOTES OF A CASE OF TÆNIA.

BY P. F. HARVEY, M.D.

THE following case is related as being of interest from the large amount of carbohc acid administered without apparent benefit.

Dr. C., a physician of middle age, consulted me April 22 of this year, on account of a tape-worm that had troubled him for a considerable period, the removal of which he had attempted but a short time previous. From several cases that I had seen reported as successfully treated with carbohc acid, I suggested this remedy as likely to destroy the parasite in his case. Concurring in my opinion, he began on the following morning by taking simultaneously one ounce of castor-oil and two pills of pure carbohc acid, each containing one grain. This dose was followed by two of the pills every two hours until sixteen had been taken. During that day there was no restriction of diet.

April 24, morning.—A powder of rhubarb and jalap, of each ten grains, was taken. One ounce of castor-oil was given at 5 o'clock P.M. At bedtime patient took two carbohc-acid pills, with three comp. cath. pills. Diet restricted to a cup of coffee for breakfast.

April 25, morning.—One ounce of sulphate of magnesium was administered, together with two carbohc-acid pills. Waited till 3 o'clock P.M.; from that time

until 9 o'clock P.M. patient took four carbohc-acid pills every two hours, making eighteen pills taken during the day. Fasted until noon, eating very sparingly then, and taking a plate of soup at 3 o'clock P.M.

April 26.—At 7 o'clock A.M. took one ounce of castor-oil, with forty-five drops of turpentine, accompanying the dose with three carbohc-acid pills. At 10.30 A.M. took one-half ounce of koosso. Fasted the entire day. At 1 o'clock P.M. passed four or five feet of tænia; at the same time he took two croton-oil pills, each containing one-half drop of the oil, and an injection of one ounce of magnes. sulph., in eight ounces of water, was administered. At 3 o'clock P.M. took one ounce of castor-oil. At 4.30 o'clock P.M. passed a *tænia medio-canellata* entire, twenty-five feet in length, and at the same time a small one, eight inches long.

Remarks.—The treatment was commenced by giving sixteen grains of pure carbohc acid, in divided doses, on the first day; ten grains were given on the second day, eighteen grains on the third day, and three grains on the fourth day; using aperients and cathartics freely, and keeping the primæ viæ free by abstinence from food. Thus within three days forty-seven grains of the pure phenic acid were given without accomplishing the dislodgment of the worm, although amply assisted by free catharsis. Both Dr. C. and myself were of the opinion that the effect of the acid upon the parasite was nearly if not quite nugatory. The koosso, aided by evacuants, acted promptly and thoroughly. In two and a half hours after its exhibition the worm began to pass, and by keeping up the evacuant action the two entozoa were passed entire within six hours after the anthelmintic had been given.

FORT PREBLE, MAINE.

NOTES OF HOSPITAL PRACTICE.

PHILADELPHIA HOSPITAL.

CLINIC OF DR. H. C. WOOD.

Reported by Dr. JOHN GUITÉRAS.

A CASE OF MILK-LEG IN THE MAN.

H. S., æt. 28, German; admitted September 16, 1874; a clerk by occupation; was engaged as a corporal in the Franco-Prussian war. Last spring he was constantly exposed to wet and cold, working as a trackman on a railroad between York and Columbia. During May he was attacked with a very obstinate diarrhœa, due to the exposure, or perhaps to the limestone water that he was forced to use. He was very much debilitated by the profuse diarrhœa, so that he was unable to work for ten weeks before the development of the present trouble. The first symptom was pain in the right knee, which was in a day or two followed by some swelling, and shortly afterwards blue and red spots began to appear over the leg. The swelling continued; the leg became very hard, and the discoloration extended until the limb became black and blue all over. There never has been much pain connected with the disease, and on the 17th, when Dr. Wood first saw him, the greater extent of the discoloration had been replaced by a marked paleness.

The leg is at present (Sept. 19) swollen, and of about the normal temperature. It might appear to be œdematous, but it is very hard, and does not pit upon pressure. This hardness is but little marked in the foot; is

much more so in the calf, becoming very decided in the lower two-thirds of the thigh. The discoloration occupies at present the inner and outer surfaces of the thigh. Four or five weeks after the appearance of the first symptoms, the opposite leg began to be affected. It is now swollen, quite pale, and the seat of patches of discoloration and of some hardness; though not to the extent of the other. He states that both the extremities retain their usual sensitiveness.

After detailing the history of the case and pointing out the present symptoms, Dr. Wood remarked substantially as follows: This man, then, after much exposure, and malnutrition, is attacked with a diarrhœa, due, it may be, to the use of hard water, and which, though not dysenteric, as shown by the absence of pain and bloody stools, is very exhausting, the stools being large and frequent. After eight or ten weeks he finds his legs affected with pain, swelling, and discoloration. About the constitutional affection and early symptoms we know nothing. He probably must have had some fever.

Now, what is the matter with this man? In the obstetric wards you have seen legs resembling this. A few days after labor, a similar condition may come on, generally affecting first the left leg, and accompanied with marked symptoms of constitutional disturbance. The pain and swelling are soon followed by excessive hardness, the limb feels like a board, and the peculiar shining whiteness of the skin has given to the affection the name of milk-leg.

Dissection has shown that the constant lesion in these cases is a thrombus, or coagulum of blood, in the veins of the affected limb. It is commonly taught that this coagulum is due to phlebitis, and very generally there is inflammation of the veins, as has been shown by post-mortem examinations; but in many cases there is simply a coagulum of blood, and no evidences of inflammation can be detected in the coats of the vessel. Along with the stoppage of the veins there is an occlusion of the lymphatics of the leg, and in some cases there are marked evidences of angioloecitis; but these are coincident phenomena, not essential to the disease. In the lying-in woman these lesions seem to be due to the passage through the veins of matters perhaps putrescent, or fragments of broken-down clots from the uterine veins. The disease affects much more frequently the left leg in women, and two explanations of this clinical fact have been advanced. In the first place, the right primitive iliac, in its course from the left side of the vertebral column to the right of the pelvis, crosses almost at right angles over the left primitive iliac vein, which is running from the right side of the column to the opposite side of the pelvis. So decided is the pressure of the right iliac artery on the left vein, that in cases where the clot extends into the iliacs there is a marked groove in the vein at this spot. Other obstetricians assert that the vessels of the left side are much more often subjected to pressure by the frequency of the left occipital positions.

The case before us is exceptional, in that the subject is a man, and in that the right leg was first affected. But it has followed the general rule that rarely one leg alone is affected, and seldom both are attacked at the same time. As in the present case, the second leg is rarely so severely implicated as the first.

As already stated, milk-leg is common in the puerperal woman, but it is rare in the male, and occurs almost exclusively in those who are broken down by excesses or are the subjects of diathetic disease. It is not very rare in advanced phthisis, where we see either milk-leg or milk-arm. Another common cause of milk-leg is cancer; why, is not positively known.

In cases of abdominal cancer, it may be thought that there is a direct propagation of the local affection or of

the inflammation excited by the cancer to the vein; but milk-leg occurs in cases of thoracic as well as abdominal cancer, so that it must be due to diathetic, not local causes.

Dr. Trousseau especially dwells upon this connection between cancer and milk-leg, and even gives to this affection of the limb a diagnostic importance: thus, he narrates a case of supposed simple ulcer of the stomach, which he asserted to be cancerous upon the supervention of milk-leg, and in which an autopsy confirmed his diagnosis. In another case of general weakness and dyspepsia, Trousseau found the same complication sufficient ground for the diagnosis of carcinoma, though no evidence of a local lesion could be detected, and he was unable to decide where the carcinoma was located. After death, a cancer of the pylorus was found, which did not mechanically interfere with the functions of this opening. In our case the liver and spleen are not enlarged, the lungs and heart and all the other organs seem healthy. In the absence of any indication of local disease, and in the fact that the patient has been always a hearty and hale man, and is under thirty years of age, are to be found sufficient reasons for discarding any fears of the existence of a malignant tumor. Looking for another cause, Dr. Wood stated that he had seen at least one case evidently due to the rheumatic diathesis. Just as there is a rheumatic endocarditis, there may be a rheumatic phlebitis. If you remember the pathology of the blood, you will know that in most of the cachexiæ there is a condition of hyperinosis or excess of fibrin. It exists in cancer, in the wasted consumptive, and in the rheumatic; and it is accompanied with a tendency to a spontaneous coagulation of the blood. As has already been stated in cancer, milk-leg is not due to a propagation of the local disease, for it occurs independently of the location of the tumor. Apparently, there are two reasons to explain the action of the cachexia of cancer and of consumption: 1, the tendency to coagulation, due to the excess of fibrin; and 2, that want of nerve-power that predisposes to inflammation on very slight causes. In rheumatism you have the system irritated by a poison which, so often lighting upon the heart, may at times light upon the veins, and you have, moreover, marked hyperinosis. Diseases have their rights as well as persons, and in the complete absence of indications of a rheumatic diathesis we cannot force the present case under that class. Finally, being unable to trace it to a traumatic origin, we are obliged to believe that the continued diarrhœa has produced a condition of cachexia in our patient, which is the sole cause of the inflammation. The involvement of the second leg seems to be due to the washing of a clot into its veins, or more generally to a propagation of the disease from the veins of the sound leg. It is evident that any loose venous clot must, however, tend rather to be carried towards the centre than the periphery. The setting loose of a solid mass in the circulation may occur in many conditions, such as heart-disease, and even sometimes in varicose veins. When a vein is occupied by a coagulum, the occluding clot always protrudes into the larger vein, and very generally offers a conical and more or less ragged end, due to the constant washing of the blood passing along the patulous vessel. A small piece may be carried into the circulation, to the right side of the heart, and thence into the pulmonary arteries, where it is at last arrested, cutting off the supply of blood from some section of the lung. If this is extensive, the patient is seized with a sudden sense of agony and mortal fear, with a terrible feeling of suffocation, which distinguishes embolism of the right from embolism of the left heart, where we have syncope instead of suffocation. If the branch occluded be large, the patient may perish in a few moments. If the patient

survive, following the infarctus, you have the symptoms of pneumonia, or of collapse of the lung,—such as dullness, cough, and bloody expectoration: there is, however, no true crepitant râle, but a coarser one. The peculiar bloody sputa may become in a day or two very fetid, and then we have a condition of gangrene.

In the stage to which the present case has arrived, there is hardly any danger of such accident occurring. The clots are pretty well consolidated, and probably the ends are dissolved and washed away. In examining this limb with a view to a prognosis of the case, we must remember the anatomy of these veins. Three sets of vessels return the blood from the lower extremities, viz., the *venæ comites*, the external saphenous emptying into the popliteal, and the internal or long saphenous, all the veins eventually emptying into the femoral vein. So that by occluding the latter you prevent almost all the return, except what may occur by anastomosis with the superficial, abdominal, and the obturator veins. Of course your prognosis depends on the chances for the blood to return: these are sometimes so small that gangrene very soon sets in. In this case there is in the right leg an intense hardness over the track of the internal saphenous vein, which affects the tissues so generally that the vessel cannot be felt as a cord, as it must have been at first. The popliteal space is also very hard, showing that this vessel must be pretty well occluded. The femoral vein feels like a hard cord, somewhat sensitive to pressure. On this same right side the impulse of the artery is less than normal, showing that the blood-supply has accommodated itself to the existing circumstances. In the left leg the trouble is mostly below the knee, the femoral vein being pretty well opened. The further history of these clots varies a good deal. The worst transformation is that they become harder and harder, uniting with the vein into a fibrous cord; the next and most general consists in an organization and contraction of the clot, and the formation of an irregular space between it and the wall; this leaves the vein partially obliterated and divided up into a series of chambers, through which the blood passes. In other cases the clot breaks up and is dissolved by the blood, owing, doubtless, to its alkalinity. In the present case there is no danger of immediate death, and it is very probable that the left leg will recover completely, and the right partially. The softening and diminution of swelling show that the blood is returning, but it will be some time before he will regain motion and the natural softness of the parts.

Treatment.—During the first stage one might be inclined to treat it as an inflammation, by antiphlogistic methods; but there is generally connected with the trouble some cachectic condition. If there is rheumatism, this should be treated. In most cases the leg is to be covered with lead-water and laudanum, and quinine to be given to sustain the system; but the period for any such treatment in our case has passed away. The leg of the patient is wrapped in cotton-wool, surrounded by oiled silk, not because it is cold, as in arterial embolism, but to produce a sort of constant vapor-bath, and bring about a condition of perspiration which may remove the serum exuded into the cellular tissue of the part. It may probably be of benefit to paint the track of the vessels with iodine, hoping to aid in the absorption of the clots. This will be done in the present case, as it is at least harmless. The man will be given abundant and nutritious diet, and we must also support his system by the administration of iron and quinine.

October 7, 1874.—Improvement commenced directly after the lecture, and has steadily continued. The patient has been kept upon the use of Basham's mixture and quinine, and has been steadily improving. To-day he is able to walk about, and, though pale and anæmic, feels much stronger. His appetite is good, bowels reg-

ular, and tongue clean. The discoloration has disappeared above the knee, and there is but a slight bluish tint below. There is some induration yet about the calf and lower part of the thigh, but this, he says, almost disappears when lying down. The left leg is almost normal. There is some pain yet in the right popliteal space, and some tenderness over the femoral vein of the same side; this has a cord-like feel, and the lymphatic glands over it are infarcted.

October 16.—Improvement has continued, and there is nothing but very slight pain and a popliteal stiffness left in the right leg. The left leg has completely recovered.

UNIVERSITY OF PENNSYLVANIA.

SERVICE OF JOHN NEILL, M.D.,

Associate Clinical Professor of Surgery.

CURE OF INVERTED TOE-NAIL WITHOUT EVULSION.

THE first case I present for your inspection and study this morning is one of "inverted" or "ingrowing" toe-nail. This is the term which is probably familiar to you all, and, although it does not truly express the nature of the affection, it is that which is in ordinary use. The affection is so common that in an audience like this there are doubtless present one or more sufferers from this malady.

The pain and suffering are often so great as to prevent the patient's walking without limping; and sometimes the toe is lost from the disease, especially when it is not properly treated.

In looking at this toe you will see that it is red and swollen at its extremity, and more especially upon its inner edge. The greatest amount of soreness is usually found at the outer edge of the toe.

Very often the edge of the toe which presses upon the side of the nail is more elevated than it is in this instance, and is covered by fungous granulations which are very sensitive, and the cleft containing the nail is filled with an offensive purulent discharge.

This affection belongs to civilized life. Savages and plantation-negroes do not suffer from it, because they do not wear tight shoes, which are really the exciting cause. The effect of tight shoes, however, is not to make the nail grow into the flesh, but to push or press the flesh over the nail. The direction of the growing nail is not so much altered as is supposed, and, instead of the nail growing into the flesh, the flesh grows over the nail. Unfortunately, the usual treatment of cutting off the corner of the nail, or slicing off the edge which is apparently at fault, only aggravates the complaint by allowing the flesh to be still farther pressed into such a position that the nail when it grows must again "grow into" it.

Not only does cutting the corners and edges of the nail do harm, but many of the remedies applied are equally injurious. Scraping the nails, cutting out V-shaped pieces from their free edges, and complete evulsion, though recommended by many surgeons, I believe to be entirely useless and attended with unnecessary pain. There is a philosophic mode of treatment which is always successful, if properly carried out; and, as we have shown that the flesh grows over the nail, the flesh is to be pushed away from the nail. In the case which is before you this treatment can be readily employed; but even in cases in which the nails are buried in pus and sensitive granulations, the result is equally certain. The time that is required for the cure depends not so much on the duration of the disease, but on the damage which has been done by cutting the nail; and the deeper and more thoroughly the offending edge of the nail has been removed, the longer will be the process of repair required.

If the nail has not been cut, it can be cured in a few weeks. If it has been cut away, it will require just long enough for the nail to grow again, which may be four months.

In commencing the treatment, first clean and dry the parts from all offensive secretions and pus. This can be done with a camel's-hair pencil, or a piece of sponge, but still better by using a small swab made by rolling a small amount of carded cotton about the end of a probe. The ordinary silver probe will not answer, because the point or bulb at its end, as you see, prevents the cotton being slipped off when it is soiled. I have, therefore, probes made out of No. 16 knitting-needles, which answer the purpose admirably. This same apparatus will also be found useful in wiping out the external meatus of the ear. The little brush of cotton can be readily made on the end of this instrument, and can be as rapidly removed after it has been used; and with it you can gently wipe the most sensitive granulations, and obtain a thorough examination of the parts. If the granulations are very luxuriant, it is best to direct our treatment exclusively to them for a few days, and they can be rapidly reduced by brushing them over with the nitrate of silver either in solid form or in solution, if this latter is the more convenient mode of application. Besides the nitrate of silver, a solution of the chloride of zinc or Monsel's solution can be used with great benefit in reducing the granulations and diminishing the discharge. After the granulations have become less sensitive, but before they have entirely disappeared, you commence the real treatment. After drying the surface with the cotton brush, it is to be covered with a layer of collodion. Then, by means of the other end of this probe, which has been flattened out and rounded into a packing instrument, a dossil of cotton is to be carefully pressed between the flesh and the nail and cemented into its place by another layer of collodion. A dossil of cotton may also be tucked under the anterior free edge of the nail and secured in the same manner if this edge has not been already cut away. This dressing will usually retain its position without much trouble; but to make it more secure a narrow strip of adhesive plaster may be applied around the toe. In two days the toe should be again dressed, but the cotton should not be removed unless it is moist and saturated with pus. After a few dressings the discharge will cease and the cotton will remain dry, and then it should not be taken out, but a fresh dossil should be thrust in alongside of that which is already beneath the nail, and coated with collodion. You will soon be able to press a wedge of cotton beneath the front edge of the nail, and bring it out beneath the side which has been pressed against so long by the fleshy granulations. After this has been accomplished, the cure is very rapid. The ordinary shoe can be worn, and the dressing need only be renewed twice a week. The patient must now be instructed in this process of packing and wedging the cotton under the edge of the nail and fastening it in its place by means of collodion, and he never need have an inverted toe-nail again, and will be thankful that you did not subject him to the painful operation of evulsion.

TRANSLATIONS.

"SYPHILIS" OF THE HARE (Bollinger, *Virchow's Archiv*, Bd. 59, Heft 3 and 4).—Up to this time no accurate observations have been made of the pathological anatomy of the disease which is seen among hares, and which is called by hunters "syphilis." Bollinger has recently had the opportunity of making post-mortem

examinations on the bodies of three of these animals that suffered from this affection. He finds that the pathological changes which result from this process consist of characteristic new growths of heteroplastic nature, which take the form of tubercles of larger or smaller size, which are principally found on the genitals, especially in the testicles and prepuce and in the uterus and ovaries, but also in the connective tissue beneath the common integument at any point. These tubercles, when seated in the testicle, have a tendency to involve the coverings of that gland, and may cause ulceration, leading to perforation.

The same tubercles are also met with in the muscles, lungs, liver, spleen, kidneys, and in the lymphatic glands of some portions of the body. When seated beneath the skin, they can also lead to penetrating ulcers which may become quite extensive. Under the microscope, these deposits at some places, by the growth of small cells which they contain, present a resemblance to tubercle as seen in man; at others they have a certain correspondence with cancer; while still another series of these tubercles have a marked similarity to syphilomata.

The tubercles which present this last resemblance are characterized by a diffuse, not sharply-defined, proliferation of round cells, which by means of outgrowths from these gradually involve the sound tissues. Another characteristic which they possess is their tendency to disintegration, so that the tubercles become partly softened and cheesy. Bollinger thinks that this disease is a constitutional one, which is transmitted by sexual intercourse, which is in many respects analogous to tubercle or syphilis in man, and is not inaptly characterized by the name syphilis which has been given it.

W. A.

OBSERVATIONS ON THE ACTION OF ERGOT (Dr. A. Wernich, *Berlin. Klin. Wochenschrift*, No. 27, 1874).—Dr. Wernich has developed a new theory of the action of ergot. This drug, according to him, does not exercise a contractile influence on the muscular coats of the arteries, or, indeed, upon organic muscular fibre in general, as has hitherto been commonly taught, but has, on the contrary, a depressing effect upon the tone of the vessels, and more especially upon that of the veins, so that the blood accumulates in them while the arterial system becomes relatively empty, and a secondary stage of contraction follows. In support of this view, he adduces the microscopic conditions which have been found in animals upon which he has himself experimented, and also the results of similar investigations which have been conducted by others. There has always been found a congestion of the venous system, while the arteries have been empty. The heart of the frog has been observed to beat more strongly while a diminished and insufficient amount of blood passes through it; and if poisonous doses of the drug are administered to the animal, this organ is found in a condition of diastole.

He thinks, further, that a critical examination as to the blood-pressure when injections of ergotin have been made will support the view that there is primarily a depression of the pressure in the arteries, followed by a gradual increase of tension. Finally, if the supposition that the first effect of the exhibition of ergot is to produce contraction of the arteries be correct, he considers it impossible to explain the curative effects of this treatment upon aneurism on physical grounds. In accordance with his theory, and supported by the well-known observations of Oser and Schlesinger, he explains the uterine contraction which results from the use of ergot by an anæmic irritation of the nervous centres whence the impulse to contractions of the uterus come.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, NOVEMBER 7, 1874.

EDITORIAL.

WHOSE FAULT IS IT?

ACCORDING to General Eaton, of the National Board of Education, during last year eight millions of dollars were donated in the United States by private citizens to educational endowments. We would like to know how much of this money went to the endowing of medical schools. Our opportunities for hearing of such donations are very good, but, so far as our knowledge extends, scarcely one dollar of the amount was given to medical schools, except what was bequeathed by Mr. Hopkins, of Baltimore. Where in this country is the medical school that has any endowment funds? Where are the salaried chairs that shall enable their occupants to accomplish some original work? Where are the medical scholarships to aid the struggles of those young men who are rich in intellect but poor in money? Colleges and universities spring up like magic; institutes of science up and down the land open wide their doors for gratuitous or partially gratuitous instruction; great sums of money, millions upon millions, are commanded for every kind of education except medical. Is any science more important than that which treats of health and life? Are education and training more necessary to the man who deals with physical problems than to him who struggles against disease and the arch-champion, death? Left to their own devices, the medical colleges savagely avenge themselves upon the people of this land by pouring forth

annually a mass of raw material, whose powers and activity for destruction the All-wise can alone measure.

To our thinking, the people are, however, to be more pitied than blamed in this matter. The profession seems slow to learn that its own salvation as well as the good of the laity demands medical endowments. More than this, many of the profession, while recognizing the needs of the hour, fail to come up to their plain duty in the matter. "Ask for money! I would not do it for the world; my patients would not stand it," or words to that effect, we have heard over and over again. Men of the widest reputation are so timid that they dare not talk face to face with the person whose life, it may be, they have saved,—dare not talk honestly and plainly as a man ought to talk to a man when the gravest interests are at stake,—men of the widest experience becoming as bashful as a hysterical girl, at the mere thought of "begging." Is this right? Does a physician lay aside his manhood when he practises his profession? In business life, the closer the relation the more freely do men speak to one another about such matters; and why is a doctor any better or any worse than a business man? Is it the man whose life is saved that does a favor to the physician by employing him, or is it the physician that confers a favor upon the patient by his skill? We have no sympathy with that unmanly state of mind which hinders its possessor from talking fairly and squarely to any man about his duty to give, and about the needs of the hour. Wisdom and tact are of course required to know when and how to approach, but there is a time and a manner for every one, and, properly done, the effort will heighten the physician in his own esteem and in that of his friends, and will bring a steady increase of influence. How many doctors are there in this city or in this country who are a living force among the people? How many are there whose influence is wasted, even to death, by want of use! If every doctor in the land were habitually looking for opportunity to speak a word in season, medical colleges would soon be among the richest. A half-dozen physicians, all with one or two exceptions very young men, in this city have within the last two years shown what might be done, by raising nearly eight hundred thousand dollars in money and land for the University Hospital. The success of this effort demonstrates that the profession needs only that its members should feel their public responsibilities, and should play their parts like men, in order to have those endowed colleges and laboratories which can alone enable it to be as a body what it ought to be.

WILL IT PAY TO DO WHAT IS RIGHT?—An enthusiastic public meeting was recently held in Boston for the purpose of raising money to build a suitable building for the Medical Department of Harvard: seventy-five thousand dollars were subscribed in the room. It was stated that the success of the new method of teaching is absolutely assured. This year about *one hundred new* students have entered for the medical course. As the fees are two hundred dollars a year for three years, an annual income of one hundred students means an annual income of from fifty thousand to sixty thousand dollars.

We believe Harvard has the only rapidly-growing class on the continent, and it apparently soon will have, if it has not even now, the *best paying* medical class in the United States.

It is stated that when the contemplated building is finished, the Society for Medical Improvement will deposit in it their valuable collections, to be used in teaching. The *Boston Medical and Surgical Journal* asserts that the Harvard School will soon be the great medical educational centre of America. If all the other schools continue to hug the delusion that in this country there is no demand for, or appreciation of, other than half-educated doctors, we fear "Ichabod" will be truly written over their door-posts, and Harvard really reign supreme in spite of the natural disadvantage of being in a comparatively small and isolated city.

NORTHAMPTON COUNTY MEDICAL SOCIETY.—Some one has favored us with a copy of the *Easton Free Press*, containing an account of the annual meeting of the Northampton County Medical Society. It is stated that a lively discussion occurred following the very excellent address of Dr. Traill Green, on the duty of the physician when patients call in a second physician before discharging or notifying the one in attendance, and without informing the second of the attendance of the first. We should think there was hardly room for discussion upon such a point. The procedure seems to us an insult to the doctor chosen as well as to the one discarded. One thing is very certain: if the physicians of Northampton County follow to the full the courses inculcated by Dr. Green, they will be like brethren dwelling together in unity.

THE WOMEN.—A school of medicine for women is about to be put in operation in London, in consequence of the earnest efforts of such men as the late Dr. Anstie, Dr. T. K. Chambers, and Mr. Ernest Hart. Among the Professors already appointed are Dr. T. K. Chambers, Practice of Medicine; Mr. Berkeley Hill, Surgery; Mrs. Garrett Anderson,

Midwifery; and Mr. Crichton, Ophthalmic Surgery. On the list of the Council we notice the names of Burdon Sanderson, Hughlings Jackson, Prof. Huxley, and Dr. W. S. Playfair. The last public act of Dr. Anstie was, as dean of the faculty, to apply to the medical examining bodies of London for recognition of the school as a duly constituted teaching body. Until this is done, the students of the school will not be admitted as candidates for degrees. The answer of the examining bodies had not been made public at the date of our latest advices. In this city the corner-stone of a new building for the Women's Medical College was laid October 1. The County Medical Society of Hartford, Connecticut, has elected a Mrs. Dr. — or a Dr. Mrs. (which should have precedence? the sign of wifehood and presumably of maternity, or that of the chosen calling?)—Ellen E. Hammond.

POISONOUS MUSHROOMS.—A recent grand jury in London rejected a bill of indictment against a gardener for causing the death of a fellow-servant by administering poisonous mushrooms. The killing was really the result of a deplorable mistake. We give, from the charge of the judge, the following tabulation of Prof. Bentley as showing the general characters separating poisonous from edible mushrooms, premising that all fungi which grow under trees are suspicious and should be rejected:

"The edible mushrooms grow solitary, in dry, airy places, and are generally white or brownish; they have a compact, brittle flesh; do not change color when cut by the action of the air; juice watery, and odor agreeable; taste not bitter, acrid, salt, or astringent. The poisonous mushrooms, on the contrary, grow in clusters, in woods and dark, damp places, and are usually of a bright color; their flesh is tough, soft, and watery, and they acquire a brown, green, or blue tint when cut and exposed to the air; the juice is often milky, the odor commonly powerful and disagreeable, and the taste either acrid, astringent, acid, salt, or bitter. These characteristics are almost invariable."

LEADING ARTICLES.

THE PRESENT STATUS OF TRANSFUSION.

THE operation of transfusion, which has for many years been hanging on the outskirts of advancing medical science, with an occasional nod of recognition from an obstetrician, or a few words of encouragement from a passing physiologist, has of late been receiving a good deal more attention than formerly, and seems

at last in a fair way to have its merits examined into and its defects carefully criticised.

During the past year the various medical and scientific journals of this and other countries have frequently contained communications on the subject, new forms of apparatus have been devised, new methods of operating have been suggested, and the procedure has been attempted under various circumstances and in a variety of diseases.

The recent accumulation of facts in this direction has, indeed, been so considerable as perhaps to render not unprofitable the task of hastily reviewing the ground already traversed and considering briefly the prospects of the operation in the future. It is, of course, impossible in an article of this kind to do more than sketch in the most cursory manner the various appliances, methods, and observations which have been put forth: we shall, therefore, only indicate some of those which seem of the most importance.

And first, as regards apparatus, we may allude to the modification of Dieulafoy's aspirator suggested by Dr. Howe,* of New York, and the somewhat similar invention of Moncoq, of Paris.† The latter is described as consisting essentially of a glass cylinder in which moves a piston. From the lower part of the cylinder two tubes proceed, containing such an arrangement of valves that the blood enters by one and escapes by the other. The object of the piston is to reproduce by its alternate movements the cardiac diastole and systole. To use M. Moncoq's expression, "It is a real heart of crystal placed between the two subjects." The blood taken directly from the vein is immediately transferred to the corresponding vein of the patient, by means of a hollow needle placed within the latter, with which one of the tubes is connected.

The great merit claimed by M. Moncoq for his apparatus is the reproduction of the cardiac movements, and the absence of all danger from coagulation, the transfusion being truly immediate. In addition, M. Moncoq claims that the risk of phlebitis through introduction of air is avoided, and, the blood being introduced slowly and by regular undulations, the organism has time to become habituated to its new conditions. It will be observed that neither of the instruments alluded to differs materially from that of Dr. Aveling, described in the *New York Medical Record*, April 1, 1874, which consists of a hollow rubber ball in place of Moncoq's glass cylinder.

In connection with these forms of apparatus, the question of mediate or immediate transfusion is of interest. According to the method introduced, we believe, by Prof. Martin, and until recently most usual, the blood taken from the veins of the giver was received in a properly-warmed vessel, deprived of its fibrin by whipping and straining, and then injected in a defibrinated condition.

M. Moncoq, however, states—and he gives this as

one of the reasons which actuated him in devising an apparatus for immediate transfusion—that careful examination of the statistics of the operation had convinced him of the impropriety of the mediate method. He asserts that a very large proportion of the cases in which defibrinated blood had been employed, terminate fatally.

Dr. Howe's reasons for using his modification of Dieulafoy's apparatus are based on similar views of the dangers and inconveniences of the mediate method.

"The blood," he remarks, "being exposed for a length of time to atmospheric influences, is liable to receive deleterious ingredients. In the process of defibrination, a quantity of red globules, the chief nutritive and stimulating element of the blood, are necessarily entangled in the meshes of the fibrin and are removed with it. In cases where the hemorrhage has been great, the time spent in defibrinating may be of vital importance. The wounds in the veins being large, there is more or less danger of phlebitis or thrombosis."

The fact is that this question is as yet undecided, well-known names being arrayed on either side. Dr. Playfair remarked at a meeting of the Obstetrical Society that the physiological fact of the uselessness of the fibrinous element of the blood in transfusion is "generally admitted." He believed, too, that defibrination is the best method of preventing coagulation, and that the use of the mediate method permits the operation to be performed leisurely, and obviates all hurry and fuss.

Dr. B. W. Richardson urged defibrination of the blood on the same occasion; while Dr. Barnes, perhaps an equal authority, expressed decided opposition to the method.

In this country, also, opposition has been expressed to defibrination, Dr. A. Flint, Jr., having stated recently‡ that unmixed blood must be regarded as the only physiologically satisfactory fluid for transfusion, while Dr. James Chadwick§ regards the presence of fibrin as indifferent.

It is to be hoped that when the circumstances and methods of the operation are finally settled, some less complicated apparatus shall be devised than those heretofore in use. With the exception of Dr. Aveling's apparatus for direct transfusion, most of the instruments in use are not likely to prove available for the general, and especially for the country, practitioner, though they may be useful in hospitals. We do not often meet with such an example of fertility of resource as was displayed by our confrère Dr. J. M. Junkin, of Easton, in the incident related by him at a recent meeting of the Pennsylvania State Medical Society.|| His account of the operation is so graphic that we wish there were space here to transcribe it in full; but we can only say that the man who, in a lonely farmhouse, performed transfusion successfully by means of

|| Medical Times, May 22, 1874.

"a glass female syringe with a curved neck, and bulb on the end of it," compels the tribute of our respect.

Concerning the use of transfusion in various forms of disease, many single cases have been recorded by different experimenters, mostly going over old ground, and inconclusive in their results. Meynert has made use of the method in cases of melancholia; Kalischer, in cholera; Klingelhofer, in gastric ulcer; and others in phthisis and other affections.

The latest investigations have taken another direction, and now the question of the day turns upon transfusion by means of blood taken from the lower animals,—a subject of too much importance to place at the end of an article, and of which we shall therefore postpone the consideration until a future occasion.

(To be continued.)

CORRESPONDENCE.

LEIPSIK, October 14, 1874.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—In accordance with the conditional promise to send you an occasional letter from this place, I forward an account of two matters which have here attracted a good deal of attention. As, however, the least conceited of us like to hear good things of ourselves, let me mention first that not long since I met the chief editor of one of the leading Berlin medical journals. He knew that I was an American, but not that I was a Philadelphian, and, in course of a conversation upon American medical matters, remarked that the *Philadelphia Medical Times* was the best American journal that came to Germany. Now to business.

To-day we celebrated here the jubiléum of Professor Ludwig, who has completed his twenty-fifth year as Professor of Physiology.

As an investigator, Ludwig is well known throughout the world; but the enthusiasm with which he has been able to inspire those who have studied under his direction, and the warm—I might almost say affectionate—feeling with which all his students regard him, must be seen to be appreciated. To-day such an occasion has offered itself, and any one who had the opportunity of being present must have been convinced that it is, sometimes at least, possible to be both investigator and teacher, in the fullest sense of the words.

At twelve o'clock assembled together in the Physiological Institute not only those who are at present students in the institution, but also many who in past years have had the benefit of Ludwig's teaching. Besides these, his contemporaries, Helmholtz and Du Bois-Reymond, as well as the venerable Weber, came to add by their presence to the interest of the occasion.

An exceedingly life-like bust of Prof. Ludwig had been executed for the occasion, and this, together with an album containing the photographs of all his old pupils, was presented to him. From Russia also came a compound of clock and inkstand, chiefly interesting

on account of certain engravings on its surface representing various instruments devised by Ludwig for the furtherance of physiological research.

There was, of course, a series of congratulatory speeches, to which Professor L. made short and feeling replies, and a number of telegrams were read from various faculties and learned societies throughout the continent.

Later, a dinner was given at the Hotel Hauße, at the commencement of which, from his place between Helmholtz and Du Bois-Reymond, Ludwig paid a tribute to the memory of those of his students who had died, and in their honor a toast was drunk in silence.

Then Ludwig's health was drunk with all the honors, and afterwards his immediate neighbors were toasted, and the characteristic speeches in which they responded were in the highest degree interesting. Prof. Weber also was addressed in the most complimentary terms, and then general toasting was carried on with most laudable activity. Dr. Kronecker, to whose exertions the very successful execution of the day's programme was in great measure due, came in for a flattering and warm demonstration.

I may be pardoned for mentioning that America was not unrepresented in the oratory of the occasion, Mr. C. S. Minot, of Boston, having made an exceedingly happy speech.

The dinner lasted until quite late, and afterwards the party was received by Professor Ludwig at his own house. In every way the celebration was an extremely interesting one, and the number of participants who came from great distances, and the success which many of them have already attained in various branches of science, went far to prove not only the estimation in which they held him whose jubiléum they celebrated, but also the great value of a sound early scientific training, even though its special direction is not that which the student eventually follows; and so to-day mathematician and physicist vied with chemist, physiologist, and anatomist in shouting "Hoch!" in honor of the teacher Ludwig.

On the 9th of October occurred the first case of cremation in Siemen's furnace, recently constructed for the purpose, in Dresden. The body was that of the wife of Sir Charles Dilke, M.P., who in her will had given directions that it should be thus disposed of. Permission was obtained from the authorities in Dresden, after deposition had been made that the cremation was regarded in the light of a scientific experiment; and the body, which had been previously embalmed in England, was conveyed to the building containing the furnace. Here it was placed in an oak coffin without a lid, and after it had been introduced into the furnace the process of incineration began, all its steps being readily observed through a door constructed for this purpose. After the lapse of six minutes the wooden coffin was destroyed; in ten minutes the external muscles were completely consumed, and in barely twenty minutes the entire skeleton was exposed, and had begun to crumble; at the end of half an hour the viscera were being rapidly consumed, and at the close

of an hour the bones were reduced to powder. Fifteen minutes later, the ashes were in a fit state to be collected for preservation in an urn. The complete incineration, if the account from which the above was extracted be accurate, was accomplished more rapidly than might have been expected from experiments previously made. The loss of watery matter which necessarily occurs during the embalming and afterwards, may account for this in some measure. Siemen's furnace consists of a fire-brick hearth or oven, with a movable iron top, which can be readily moved aside to admit of the introduction of the body, which is lowered in from an upper story, where the funeral party are assembled. The heat is obtained through the burning of a mixture of gas and air, which is at first caused to heat the hearth from the outside, until most of the moisture is driven off from the body, and afterwards conducted directly into the chamber itself. As soon as charring is thoroughly accomplished the gas is turned off, and merely heated air passes through, the carbonized and glowing mass being thus rapidly supplied with oxygen, and, of course, rapidly consumed. Under ordinary circumstances the first or drying-out part of the process lasts from an hour to an hour and a half, and the whole process perhaps three hours.

October 28, 1874.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR MR. EDITOR,—Your remarks upon medical education always appear to me laden with meaning of the deepest importance both to the profession and to the general community, and I sincerely hope you may never weary of the subject so long as anything in the way of improvement is left unattained.

But a paragraph which I saw in the *Times* of the 17th instant bears so strongly upon the same subject that I have ever since been looking in vain to see some allusion made to it in your editorial columns. The paragraph I allude to is copied from the *Homœopathic Review*, and is headed "Slow Progress of Homœopathy in Great Britain." It states, *inter alia*, that there are eighty-seven towns of from ten thousand to one hundred thousand inhabitants in England which have no homœopathic physician.

However much the blessed state of those eighty-seven towns is to be envied, I greatly doubt if they have any equals in this country. Every one knows our deplorable condition in this respect. But how is this state of affairs to be explained? Simply by the fact that in England the average practitioner is a man of much higher professional attainments than the average doctor in this country.

Although homœopathy and gross ignorance of everything which really makes medicine a science may be regarded as convertible terms, yet this fungus has grown to its present enormous proportions in our midst just because in a large proportion of cases—how large I believe it to be I dare not say—the physician does

more harm than good with his drugs, and the homœopathist gains a reputation for success by leaving his patient severely alone.

On the Continent, homœopathy has made even less progress than in England, and for the same reason; and although this medical mysticism was originated by a German enthusiast, it has never succeeded in effecting a lodgment in the land of its birth,—that land of enthusiasts.

The spread of homœopathy in this country is to the medical profession a handwriting on the wall, with a finger pointing to a warning TEKEL.

If our schools were based upon a system similar to that of the German universities, homœopathy would soon be numbered as one of the errors of the past.

Very truly yours,

S. Q. LAPIUS.*

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THURSDAY EVENING, OCT. 8, 1874.

THE PRESIDENT, DR. WM. PEPPER, in the chair.

SCLEROSIS of the posterior columns of the spinal cord.

Dr. R. M. BERTOLET presented two specimens of this condition, which will form the subject of a later communication to the *Philadelphia Medical Times*. Also, sections under the microscope of the spinal cord presented at the last session, which had been compressed by syphilitic gummata encroaching upon the bodies of the vertebræ.

Dr. PEPPER said that he enjoyed the opportunity, while in Paris, of examining many of Charcot's preparations of the spinal cord at the Salpêtrière, from which the true lesions of infantile paralysis had first been demonstrated. The number of carefully-made observations has now so much increased that it is no longer questioned that one form of infantile palsy depends upon this lesion of the groups of nerve-cells in and near the anterior horn of gray matter.

In regard to this case of sclerosis of the posterior columns, the lesion was the usual and characteristic one of progressive locomotor ataxia, and he believed that the patient from whom the specimen had been obtained, and who had been under his care for some months before his death, had first presented the symptoms of that disease soon after his penis and scrotum had been amputated by a single stroke of a large knife, occasioning copious hemorrhage.

Dr. HARRISON ALLEN did not know whether Dr. Pepper supposed that any relation existed between the peculiar accident and the phenomena of the paralysis, but he thought it not unreasonable that there should have been, conceding the announcement of a favorable predisposing condition. The surgical shock of such

* The editors of the *Times* do not hold themselves or the paper in any way responsible for the statements of correspondents, but only for the fact that correspondents are men of standing in the profession. The columns are open alike for all shades of opinion in regard to professional matters. Editors are as apt to be mistaken in their views as other men of equal judgment and opportunities. By free discussion only can reforms be brought about in a country constituted as is the United States.

an operation, particularly if the organs were excited, must have been very considerable, and could readily have extended to the spinal cord.

Epithelial cancer from the male urethra.

Dr. J. E. MEARS presented a secondary growth from the meatus urinarius of a man aged 40, which was referred to the Committee on Morbid Growths, which reported, October 22, as follows:

"Dr. Mears's tumor removed from the urethra is an epithelial cancer. The papillæ are covered with dense layers of larger flat epithelia, and contain concentrically laminated pearls."

Aneurismal perforation of trachea.

Dr. R. M. BERTOLET presented the specimen, from Annie S., æt. 34, who was admitted to the Philadelphia Hospital but a short time before her death. She was suffering with chronic bronchitis; had a dry hacking cough; slight expectoration, at times tinged with blood; voice very hoarse, often completely aphonic. No radial pulse could be detected in left wrist. Upon Sept. 10 the resident physician, upon his visit, found her sitting in a chair, complaining of feeling a little indisposed. Shortly afterwards, she suddenly fell to the floor, and was expiring by the time the physician—still in the ward—reached her. Spasmodic respiratory efforts were made at long intervals, with blood flowing from her mouth and nostrils. She was dead in less than two minutes.

Autopsy had to be limited to the thorax. Internal surface of the manubrium of the sternum is slightly eroded by the pressure of the aneurismal sac. Lungs are apparently healthy; smaller bronchi filled with clotted blood; valves of the heart competent. The aorta is atheromatous. An aneurismal sac, about the size of a hen's egg, filled with laminated coagula, arising from the transverse arch of the aorta, and partially involving the innominate branch, has greatly compressed and flattened out the anterior wall of the trachea, one inch above the bifurcation. Several of the cartilaginous rings are eroded at this point, and the underlying mucous membrane is perforated. A large clot, extending into the bronchi, is found adherent to the margins of the ulcerations. The tracheal and bronchial mucous membranes are highly inflamed and thickened. A secondary dissecting aneurismal tumor, of nearly the same size as the first, has formed upon the ascending portion of the aorta, and is likewise filled with a clot. The right recurrent laryngeal nerve is firmly adherent to the aneurismal tumor. Most probably its compression was attended with paresis of the right vocal cord, thus accounting for the troubles in phonation. Unfortunately, no laryngoscopic examination was made.

Dr. ALLEN said that the specimen was one of a very interesting class. He alluded to a case reported by Mr. Fullerton, in which an aneurism of the arch of the aorta passing up between the trachea and œsophagus actually ulcerated into both. Hæmatemesis and hæmoptysis had occurred during life.

Cystic liver from a rat.

Dr. A. C. W. BEECHER presented the specimen, for Dr. ISAAC E. ROBERTS. The rat was found dead, lying in the middle of the cellar floor. Because so found although no poison had been laid for rats, curiosity as to the cause of apparent sudden death led to the post-mortem examination.

The rat appeared to be an old one, was well nourished, but not fat. When opened, the stomach was found distended to its utmost capacity with material resembling moist dirt, having no appearance of food. The intestines were entirely empty. It was neglected to observe whether or not there was an obstruction at the pylorus. The liver was covered with cysts about the size of a pea, each cyst containing a worm

from one and a quarter to one and a half inches long. The liver-structures seemed to be healthy. The specimen was referred to the Committee on Morbid Growths, which reported, October 22, 1874:

"In each of the numerous cysts contained in the rat's liver presented by Dr. Beecher, was found coiled up a single worm, averaging fully an inch in length, with numerous transverse segments (over a hundred proglottides were counted in a single specimen). The caudal joints are contracted and filled with ova. The double row of hooklets upon the head, numbering thirty-two in all, each supplied with the characteristic claw, determines this parasite to be a *tænia solium*."

Acute pericarditis; hypertrophy of heart from pre-existing disease.

The PRESIDENT presented the specimens, from James —, æt. 9; was admitted to the Children's Hospital on September 21. Only very imperfect information of his past history could be obtained. It was stated that he had had symptoms of rheumatism two weeks previously, and that on former occasions he had had attacks of that disease. No symptoms of heart-trouble had been noticed. On admission, there was no swelling or tenderness of any of the joints. There were orthopnoea, great præcordial distress, complete anorexia, and marked general prostration. The pulse was small, quick, and irregular, averaging from 140 to 160 per minute. There was slight præcordial bulging; the area of cardiac dullness was greatly extended, reaching from third rib down to line of apex in sixth interspace, and extending from right margin of sternum to left of line of left nipple. This was evidently due to hypertrophy of the left ventricle, as the impulse was heaving and extruded and reached as far as the lowest limit of dullness. A thrill was felt near left border of sternum. On auscultation, a strong systolic mitral murmur was detected, together with very marked churning and rubbing friction-sounds, whose seat of greatest intensity was along left border of sternum.

He was treated with small doses of calomel (gr. $\frac{1}{4}$ to gr. $\frac{1}{2}$) frequently repeated and pushed to mild salivation; tr. digitalis, gr. v every four hours; blisters to præcordia, absolute rest, nutritious fluid diet, and f3i brandy four times a day. He improved quite rapidly, and in the course of ten or eleven days was able to sit up in a chair, with quite easy breathing, pulse of 85 to 90, fair appetite, no præcordial pain, and diminishing murmur and friction-sounds. Unfortunately, owing to a sudden change in the weather, or to imprudent exposure, he contracted pleuro-pneumonia of the left side on the twelfth day, and died in forty-eight hours.

At the *autopsy*, a moderate amount of pleuritic effusion was found on left side, with consolidation of lower lobe of left lung. The pericardial sac was greatly enlarged: on being opened, it was found to contain four fluid-ounces of blood-stained hæmatin. There were signs of intense pericarditis; around the apex and for a distance of one and a half inches up the body of the heart, the two serous layers were matted together by grayish glutinous lymph. The rest of the serous membrane was coated with false membrane, for the most part not very thick, and with reticulated arrangement. Corresponding to seat of most intense friction-sound were two large patches (one on each layer of the pericardium) of firm lymph, arranged in parallel transverse ridges. The heart was greatly hypertrophied, weighing, with the pericardium attached, over eighteen ounces. There was marked thickening of walls of left ventricle, with considerable dilatation of cavity. The mitral valves were thickened, and their edges fringed with small vegetations. The aortic valves were competent, but were slightly thickened, and had a row of small vegetations on their ventricular surface, near the free border of the leaflets.

GLEANINGS FROM OUR EXCHANGES.

EMPHYEMA TREATED BY FREE INCISION (*The Boston Medical and Surgical Journal*, October 22, 1874).—Dr. J. T. Boutelle reports the case of a boy, æt. 19, who, after repeatedly catching cold, was compelled to take to his bed, with fever, severe pain in right side, etc. When first seen, he had been in this condition for six weeks, was greatly emaciated, had a marked hectic flush, and was sweating profusely both night and day. The physical signs showed that there was a large collection of fetid pus in the right pleural cavity, and an opening in the lung itself near the apex. He was first tapped with an aspirator between the seventh and eighth ribs, about two inches from the lower angle of the scapula, and three pints of brown, fetid, thick, frothy pus were removed. Stimulants and nutrients were ordered in large quantities, and his condition improved somewhat. Four days later, an operation was performed for the purpose of establishing permanent drainage. A knife was passed between the eighth and ninth ribs, about an inch to the right of the lower angle of the scapula, into the pleural cavity, and the incision slightly enlarged on withdrawing the blade. No pus escaped. An india-rubber drainage-tube was then pushed in about five inches, and secured by straps of adhesive plaster. The pump of the aspirator was attached to the tube, but no pus could be drawn through. After injecting a little warm water, without helping matters, the tube was drawn out, the clots were removed from its calibre, and it was re-introduced, but still no pus could be drawn through it. The tube was removed, and a canula introduced, but with no better result. As the patient was growing very weak, crying out with pain, and threatening to faint, the canula was removed, and a poultice applied over the incision.

After an interval of five days, during which his condition rather deteriorated, it was decided to give ether, and to make an opening between the ribs large enough to give exit to pus. A trocar was thrust between the seventh and eighth ribs, at the point where pus had been first found, and, as it began to flow through the canula, the latter was removed, and an incision three inches long was made through the skin, the point of puncture being at the middle of the incision. A careful dissection was made down to the pleura, the cavity of which was opened by an incision of two and one-half inches. About three pints of fetid pus escaped. On examination with the finger, a long, smooth line of adhesion was found a few inches below the incision, passing downward and backward, evidently the bottom of the sac of the abscess.

For nearly two weeks after this operation he continued to do well, his appetite being much improved. It was then found, however, that the opening in the pleura had entirely closed by granulations. The patient was again etherized, the union was easily broken up with the finger, and an opening made the length of the original incision. Not much bleeding. About a pint and a half of excessively fetid pus escaped. A rubber tube was then inserted, and the cavity thoroughly syringed out with warm water containing a trace of carbolic acid. The tube was then fastened in by adhesive strips.

The same treatment was continued, the thorax being washed out daily with warm water; but the patient gradually sank, and died about three weeks after the last operation. No traces of tubercle were found in the lungs.

Dr. Boutelle calls attention to the following points:

The condition of the patient; the long duration of the disease; the excessive sweating, painful bed-sores,

and general prostration rendering it a most unfavorable case for operation.

The immediate relief and gain in strength which followed the evacuation of the pus, the general condition steadily improving up to about two weeks before his death.

The rapidity with which the large incision granulated together, which shows the necessity of guarding against this at the time of operation, by stuffing with lint, or inserting tubes.

The absence of tubercular deposit in the lungs after so much inflammatory disturbance.

The result of the second operation, when no pus was evacuated, showed that it is not *always* safe to enter the thorax very low down. The autopsy showed that this point was nearly two inches too low to enter the cavity.

DEATH FROM THE ENTRANCE OF VOMITED MATTER INTO THE LARYNX (*The Lancet*, October 3, 1874).—Mr. W. W. Smyth reports the case of a child, four years of age, who was under treatment for two small abscesses of the scalp. A small opening was made in one, and the contained matter gently pressed out. During the performance of this trifling operation the boy began to cough, and showed symptoms of suffocation, which were attributed to spasm of the glottis. He revived a little, and was carried to a bed, but in a few minutes the attack returned. He was given nitrite of amyl by inhalation, followed by artificial respiration and electrical stimulation, and, these failing, by tracheotomy. This was also of no avail, and the child soon died. There was no history of his having had anything in his mouth, and nothing could be discovered by careful examination, but the autopsy next morning revealed a piece of partially digested mutton, about the size of a bean, in the larynx, and the right bronchus full of vomited matter. The stomach had evidently thrown up its contents during the opening of the abscess, and, fear paralyzing or otherwise interfering with the sentient apparatus of the glottis, the vomit had been allowed to enter the windpipe.

DISLOCATION OF THE SPINE (*The Irish Hospital Gazette*, October 1, 1874).—Dr. F. W. Warren reports a case of injury to the spinal cord, produced by indirect violence applied to the vertex. There was a displacement forwards of the fourth and fifth cervical vertebrae, with laceration of the inter-vertebral substance. There was at first complete paralysis of motion, including the upper extremities, with partial anæsthesia. Reflex phenomena were excitable in the lower limbs, and there was slight recovery of motion in the toes twelve hours subsequent to the receipt of the injury. Death occurred in about thirty-two hours, being preceded and followed for one hour by a very high temperature, ranging from 103° to 105° Fahr.

SUPPURATIVE INFLAMMATION OF THE GALL-DUCTS (*The Lancet*, October 3, 1874).—Dr. William Bates, F.R.C.S., a distinguished English physician, recently died, after a final illness of only three days. He had, however, been a great sufferer for several years from the passage of gall-stones, and from coincident epileptic seizures. During his last sickness there were jaundice, retention of urine, and coma, but no pain or tenderness over the liver. A post-mortem examination was made twelve hours after death, and the following interesting appearances were observed:

On making an accidental incision into the liver, bubbles of gas escaped freely; the blood was fluid everywhere. On exposing the liver, which was very large, the surface appeared like polished port-wine-colored marble, many patches of lobules, well defined, being more deeply colored than the rest. But what attracted special notice were aggregations of whitish spots here and there, some of them being slightly raised,

suggesting at once disseminated cancer. They proved to be the terminations of dilated bile-ducts filled with pus; some were quite as large as peas, and looked like round cysts on incision. On the concavity of the right lobe, the ducts in one place were enlarged to the size of one-eighth of an inch in thickness, and presented whitish branchings, just like bluish branchings produced by liver flukes. One long white patch was found to be an old cicatrix. The gall-bladder was concealed by old adhesions to the omentum and mesocolon. On dissection, the common duct was found to be so much enlarged that it appeared almost exactly like a portion of small intestine. The gall-bladder was enlarged but not distended. It contained many small black polyhedral calculi, like those which were passed during life, with a thin fluid containing brownish flakes resembling faecal matter rather than bile. The hepatic duct was distended by two large and irregularly-shaped calculi for about two inches and a half; they were each about the dimensions of a bantam's egg, though not the same in form; many projections on each were impacted in enlarged ducts which opened into the hepatic; had they been smooth and roundish, the common duct would have been quite capable of allowing them free egress. All the ducts everywhere were proportionately dilated, and contained calculi of every intermediate size, from marbles to large grains, just like renal lithic gravel. Literally, reckoning these, there were thousands of calculi.

The enlarged ducts were traced, without any difficulty, but simply by free incisions, to the white spots already mentioned.

MISCELLANY.

THE CRY OF THE CHILDREN.—Public attention in France has been much directed of late to the great decrease in the population during the last eight years. The census of 1872 shows a diminution of 370,000 since the census in 1866. Among the causes assigned for this remarkable decrease are, the enforced celibacy of the large standing army of France, the diminution of births in the marriage state, and, lastly, the excessive mortality among infants. One of the first medical men who called attention to this neglect, M. Brochard, affirmed in 1866 that, reckoning pauper children, 100,000 nurse-children die annually in France of hunger, privation, want of proper care, and want of superintendence. The Academy of Science endorsed this statement by crowning the work in which it was embodied. Soon after, M. Felix Boudet renewed this sad accusation, by declaring before the Academy of Medicine that France loses every year by its own fault 120,000 young infants under one year old. This first stage of life gives a considerable proportion of death-rate everywhere, and an eminent statistician has given striking expression to this fact in the observation "that a new-born infant has less chance of living for a week than a man of ninety, and less chance of living a year than a man of eighty." In France, however, in ordinarily favorable vital conditions, M. Bertillon calculates that, up to one year of age, the death-rate averages 21.7 per 100; that is to say, more than a fifth of the children born die at the end of the first year. In Paris, out of 54,000 children who are born every year, nearly half die before their fourth year; and if the children

sent out to nurse be reckoned separately, it will be found that at least one-half (51.6 per 100) have perished in the first year of their life. Finally, if the children be classed according to their position in life, and the kind of nurse with whom they have been placed, the almost fabulous death-rate of from 75 to 80 per cent. is attained, which seems incredible even when we find it stated in official records. The Academy of Medicine has taken up this terrible blot on the civilization of France, and has issued a code of laws for the protection of infant life. Among the causes mentioned in this programme as productive of the general mortality, and which may be reached by legal enactments, are the following: The want of a system for the verification of the deaths of new-born children and nurse-children; the premature taking-out of infants for the purpose of obtaining the certificates of birth and baptism; the putting them out to nurse; the default of measures making vaccination obligatory; the absence of any law to regulate taking children in to nurse, and especially for any administrative and medical watching over the nurse-children; the persistence, especially in country districts, of injurious practices and prejudices, kept up by ignorance, respecting the care required by the children, and the adoption of the system of feeding the children too soon by hand.—*London Medical Record*.

NUTRITIVE MEAT-JELLY COMMENDED BY DR. ANSTIE.—Lean beef fillet, three pounds; lean veal, three pounds; lean mutton, three pounds; cut up small and put into a saucepan *with no water*; simmer (never boiling) by the side of the fire for eight hours; strain the liquid (from a small quantity of tasteless, insoluble fibre that remains), and let it jelly into a soft mass. This is an immensely concentrated *meat*, minus very little but the water which has been driven off; a teaspoonful or two of it is a wonderful support, and can be taken every hour with ease.

THE CHAMPION CHLOROFORM-TIPPLER.—Dr. W. W. Parker related, at the last meeting of the Virginia State Medical Society, the case of a man named Johnson, a blacksmith, who became addicted to chloroform-tipping. How much in quantity he swallowed is not stated, but he bought and drank three thousand dollars' worth in three years! His mind then became affected, and he imagined himself tricked. Meanwhile he fattened fifty pounds, and on ceasing the habit lived fifteen years in good health, and died from natural causes.—*The American Journal of Dental Science*.

THE death is announced of Dr. Arthur Jacob, of Dublin. He was born in 1790, and was the author of numerous papers on medical subjects, but his memory will be chiefly kept alive by the "membrana Jacobi" of the eye. He was the founder and original editor of the *Medical Press and Circular* of Dublin.

ONE hundred and thirty thousand pounds of bromine are stated to have been manufactured in the Ohio and Kanawha Valleys last year. One thousand pounds were produced in Pennsylvania.

IODINE CAUSTIC is prepared by dissolving four grammes of iodine in eight grammes of glycerin. It is used in lupus by applying it once every other day, and covering the parts with gutta-percha. This treatment is continued for several weeks.

NOTES AND QUERIES.

AMERICAN PUBLIC HEALTH ASSOCIATION.

The American Public Health Association will convene in Philadelphia, Tuesday, November 10, 1874, in accordance with the adjournment of the Annual Meeting. The following Order of Business has been adopted by the Executive Committee in compliance with Article XII. of the Constitution of the Association:

The meetings will be held at the College of Physicians, corner of Locust and Thirteenth Streets, Philadelphia.

ORDER OF BUSINESS.

Tuesday noon, November 10. The Session commences at noon.

- (1) Registration of Members and others in attendance.
- (2) Introductory Remarks by the President of the Association.
- (3) A Paper on Excessive Infant Mortality in Cities, and the Means of its Prevention, by Prof. Henry Hartshorne, M.D., of Philadelphia, Pa.
- (4) A Paper upon the Influence of Hereditary Diseases upon the Health of the People, with Suggestions of Methods of Prevention. By J. R. Black, M.D., of Ohio.
- (5) The Health of Tenement Populations, and the Sanitary Wants of their Dwellings. By Edward H. Janes, M.D., of New York.
- (6) A Report upon the Death-Rate in Towns of Michigan; and comparison of these with Dr. Farr's *Life Tables* of Health Districts of England. By H. B. Baker, M.D., Secretary State Board of Health of Michigan.
- (7) A Report upon Hospital Construction. By J. S. Billings, M.D., Assistant-Surgeon U. S. Army.
- (8) A Paper upon Hospital Architecture and the Perfect Ventilation of Hospital Wards. By Carl Pfeiffer, F.A.I.A., of New York.
- (9) Conference of Sanitary Officers and others upon Methods and Experience in the Public Health Service.

[Closing at 6 P.M.]

DISCOURSES: TUESDAY EVENING.

First Discourse, by Rev. Samuel Osgood, D.D.: *The Relations of Health and the Higher Culture.*

Second Discourse, by Hon. L. H. Steiner, M.D., of Maryland: *Health a Prerequisite of National Success in Peace and in War.*

Third Discourse: *The Sanitary Relations of Hospitals, and the Economy of Perfect Care of the Sick and Hurt.*

WEDNESDAY, NOVEMBER 11.

- (1) 9 A.M. Business Meeting and Reception of Voluntary Papers, etc.
- (2) A Paper upon the Ground in Relation to Diseases. By Edwin M. Hunt, M.D., President of the Sanitary Commission of New Jersey.
- (3) A Report upon the Deterioration of Vegetables and Fruits, as connected with their Gathering, Transportation, Storage, and Marketing. By S. C. Bussey, M.D., Washington, D.C.
- (4) A Report upon the Sanitary Government, Vital Statistics, and the Methods of Public Health Administration in the Cities and large Towns of North America. By E. Harris, M.D., of New York.
- (5) A Paper upon the question—Does Smallpox become Epidemic, or is it spread solely by its own Contagious Property? By Edwin Snow, M.D., Superintendent of Health, Providence, Rhode Island.
- (6) A Report upon Yellow Fever on the Dry Tortugas. By Harvey E. Brown, M.D., Surgeon U. S. Army.
- (7) 2 P.M. A Discourse by S. D. Gross, M.D., LL.D., D.C.L., Oxon, upon *The Factors of Disease and Death after Injuries, Parturition, and Surgical Operations.*
- 4 P.M. A Conference upon Laws and Methods of the Public Health Service of the different Cities and States. By Officers and Members of Boards of Health.

DISCOURSES: WEDNESDAY EVENING.

First Discourse: By Prof. Charles F. Chandler, M.D., LL.D.: *Practical Applications of Chemistry in the Public Health Service.*

Second Discourse: By Prof. Edward Orton, President of the Ohio Agricultural College: *Certain Relations of Geology to the Water Supplies of the Country.*

Third Discourse: By Gen. E. L. Viele, Civil Engineer: *Principles and*

Practice in Drainage and Sewerage, in connection with Water Supplies.

THURSDAY, NOVEMBER 12.

9 A.M. Business Meeting and Election of Officers and Committees.

(1) State Medicine the Basis for the Elevation of the Standard of Medical Education. By Stephen Smith, M.D., of New York.

EXECUTIVE COMMITTEE:

President, Stephen Smith, M.D., New York; *First Vice-President*, Edwin M. Snow, M.D., Rhode Island; *Second Vice-President*, C. B. White, M.D., Louisiana; *Secretary*, Elisha Harris, M.D., New York; *Treasurer*, John H. Rausch, M.D., Illinois. S. O. Vanderpool, M.D., N.Y.; Edward Jarvis, M.D., Mass.; J. M. Toner, M.D., D.C.; Moreau Morris, M.D., N.Y.; J. J. Woodward, M.D., U.S.A.; A. N. Bell, M.D., N.Y.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A CONVERSATIONAL meeting of the Philadelphia County Medical Society will be held Wednesday, November 11, at 8 o'clock P.M.

Dr. H. Lenox Hodge will read a paper on the subject of Excision in Hip-Joint Disease.

All regular practitioners of medicine in the city are invited.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM OCTOBER 27 TO NOVEMBER 2, 1874, INCLUSIVE.

SUMMERS, J. E., SURGEON.—Assigned to duty as Medical Director of this Department. G. O. 19, Department of the Platte, Oct. 24, 1874.

The following-named officers will report in person to the President of the Army Medical Board, now in session in New York City, for examination for promotion, and, on its completion, rejoin their respective stations: Assistant-Surgeons Albert Hartsuff, J. H. Janeway, J. R. Gibson, J. M. Brown, H. E. Brown, and Elliott Coues. S. O. 233, A. G. O., October 27, 1874.

KNICKERBOCKER, B., ASSISTANT-SURGEON.—To report in person to the President of the Army Medical Board, now in session in San Francisco, for examination for promotion, and, upon its completion, rejoin his proper station. S. O. 233, c. s., A. G. O.

CRONKHITE, H. M., ASSISTANT-SURGEON.—Relieved from duty in Department of the South, to report in person to the President of the Army Medical Board, New York City, for examination for promotion, and, upon its completion, to the Commanding General, Department of Arizona, for assignment to duty. S. O. 233, c. s., A. G. O.

ROSE, GEORGE S., ASSISTANT-SURGEON.—Relieved from duty in Department of Arizona, to report in person to the President of the Army Medical Board, New York City, for examination for promotion, and, upon its completion, by letter to the Surgeon-General. S. O. 233, c. s., A. G. O.

ELBREV, F. W., ASSISTANT-SURGEON.—Granted leave of absence for six months, with permission to go beyond sea. S. O. 234, A. G. O., October 28, 1874.

MATTHEWS, W., ASSISTANT-SURGEON.—Assigned to temporary duty at Fort Hamilton, New York Harbor. S. O. 213, Military Division of the Atlantic, October 28, 1874.

DICKSON, J. M., ASSISTANT-SURGEON.—To report in person to the President of the Army Medical Board, New York City, for examination for promotion, and, upon its completion, to the Commanding General, Department of the South, for assignment to duty. S. O. 233, c. s., A. G. O.

SATURDAY, NOVEMBER 14, 1874.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON THE USE OF DIGITALIS IN DISEASES OF THE HEART.

No. I.

Delivered at the Philadelphia Hospital

BY H. C. WOOD, JR., M.D.

Reported by Dr. JOHN GUITÉRAS.

THERE are, gentlemen, primary physiological facts concerning the action of digitalis which I shall to-day lay down somewhat dogmatically as the premises for the discussion of the subject. I do this because time is wanting in which to give you the proofs of these premises, even if they were not out of place in a clinical lecture-room; and I do it the more willingly because those of you who may be inclined to be skeptical can find these proofs in detail in my treatise upon therapeutics.

By experiments on the lower animals two things have been definitely ascertained: 1, that in the lower animals digitalis is a very powerful stimulant to the inhibitory apparatus of the heart; and 2, that it is also a powerful stimulant to the muscular substance or its contained ganglia.

We know the first because after the administration of the drug, when the heart has already been affected by it and is beating slowly, if the inhibitory nerves be cut, the organ springs, as it were, into an intense rapidity of action. The drug stimulates the cardiac muscle, because the amount of work performed by the heart is vastly increased under its influence, even when the viscus is disconnected from the body. We also know as a probable fact that digitalis causes a general vaso-motor spasm, a contraction of the muscular walls of the vessels. Thus much for the observations made on the lower animals.

When digitalis is administered to man, the first thing we observe is a diminution in the number of heart-beats and an alteration of the character of the pulse, which becomes full, and hard, and strong. You can recognize by the feel of the blood-wave that both the force of the contraction of the heart and the amount of blood thrown out during the systole are increased. If the drug is given in poisonous doses the pulse may, it is true, become rapid, and smaller than normal. The meaning of this can be explained by referring again to the animal. We find that here the same phenomena are observed, and that if a very large dose is given the heart may be suddenly arrested in systole from irritation of the cardiac muscle; before this happens, for a time, the tendency to contract is so great that the systole will occur before the complete filling up of the cavities. Two short imperfect waves are thus produced instead of one long one: this is the double beat, forming a dicrotic pulse. In man the "dicrotic

pulse" of digitalis is classical, and its mechanism is evidently the same as that of the double arterial wave in the lower animals: instead of a long pause and a full dilatation, the first attempt at diastole is interrupted by an abortive systolic contraction. As in animals, probably in these cases also, the apex of the heart scarcely relaxes at all. Again, a person under the influence of digitalis may have a heart beating 50 or 60 per minute when in the recumbent posture, but on sitting up the pulse may suddenly become weak and mount to 100 or 120. The action of digitalis has been carried in such a case to the point at which an excess will throw stimulation into overstimulation and imperfect contraction. The act of rising brings an extra strain on the heart, and the muscle loses its power of regular action.

Digitalis, then, in man, by its action on the inhibitory apparatus, prolongs the period of diastole, thus giving time for the ventricles to fill up with more blood than usual, and also increases the muscular power of the heart, so that when it contracts a greater volume of blood is thrown with a greater force into the arterial system. Before we begin to apply these principles, remember also that the vascular system under the control of the vaso-motor nerves is probably kept in a state of contraction by the influence of digitalis.

Almost nothing but common sense is needed now to apply these facts to the treatment of heart-diseases. If what has been said is true, digitalis ought to be useful when there is a deficiency of heart-power. Remember that it is not a rag that will stop up a leak; and do not fall into the common error of expecting the drug to perform impossibilities. It cannot tighten a leaking valve. It cannot open and smooth down a contracted orifice. In other words, in valvular lesions it can only indirectly remedy the defects; and, although often you will get the most surprising results from its use, yet in every case of valvular lesion there comes, sooner or later, a stage when digitalis is powerless. It is when the valves are healthy, and the cardiac failure is due simply to weakness of the muscular walls, that digitalis exerts its most wonderful powers. Nothing is more marvellous in clinical medicine than the relief you can sometimes rapidly afford in cases of simple dilatation of the heart. The following extract from my private note-book will probably do more than any declamation to impress this fact upon you:

Mr. D., æt. 55, when first visited in the morning was found in a condition of intense cardiac dyspnoea. There was no cardiac murmur, and nothing to indicate a valvular lesion; but the heart-sounds were very feeble, and the impulse was exceedingly weak and fluttering; its area as well as that of the percussion-dulness was widely extended. The urine was albuminous, and the patient was passing only three or four ounces in the twenty-four hours. The sick man sat during the whole day and night leaning against the back of a chair, struggling for breath. He would fall asleep for an instant, the respirations becoming feebler and more and more distant, until the face grew livid and death-like, when suddenly he would awake with a violent

start, and enter upon a succession of labored, gasping, struggling respirations. In three or four minutes he would become quiet; then the respirations would grow slower and slower until at times they would be entirely suspended for nearly a minute, when he would awake with a start as before. For several weeks, under the care of a notorious dispenser of diluted nothings, this man had spent in this manner nights and days of horror with death staring him in the face. He assured me that he had not been conscious of sleeping for over a week, and that he only wanted to get sufficient relief to allow him to get to his home in the far West and make some business arrangements before going the long journey. He was ordered fifteen drops of tincture of digitalis every two hours. At the end of twelve hours the effects were already manifested. The pulse had fallen from 102 to 94, and it was fuller and stronger than before. The agony of the spells was slightly relieved by the administration of morphine. Quinine and stimulants were also given. In the next twenty-four hours seventy-five drops of the tincture were given, and the pulse fell to 84 and became full, strong, and regular. He passed over a pint of urine. During the ensuing night the patient took no digitalis, and his pulse was not so strong in the morning as it had been, although only 86; during the day following he was given forty-five drops of the tincture; in the twenty-four hours he passed one and a half pints of urine.

Not to weary you with details, I will tell you that, continuing the use of the drug, in the course of two or three days the spells of dyspnoea almost disappeared, and he was able to sleep in his bed. In a few weeks this man returned to Omaha, where he died suddenly a few weeks later.

Let me give you, gentlemen, another lesson from my note-book:

A physician leaving town for a few days asked me to take charge of a lady patient of his, whom we found in our visit together very much in the same condition as the case just described. She had been taking five or ten drops of tincture of digitalis three times a day. I suggested a large increase of the dose; and my friend, turning to the patient, said, "Doctor, this woman has been in this chair many weeks; I have done all I could for her, but life is a heavy burden to her: she wants to die. You can't do more than kill her: if anything offers a prospect of relief, she wants it, no matter what are the risks. She is well pleased to have you kill her." The patient nodded acquiescence. It was the strangest scene I ever witnessed in a sick-room. Digitalis was therefore ordered in large and constantly-increasing doses. The result was that, a few weeks subsequently, when my colleague returned and rang the door-bell of the house, this woman came down from the third story to let him in.

The dilated heart is weak, and also is embarrassed by that weakness. Owing to its want of power, the circulation begins to fail; then instantly through the nervous system come the demands from all the tissues: more blood, new blood, better blood, is wanted. The heart is irritated beyond measure; it gets flustered, as it were, and its beats become rapid, irregular, and even more inefficient than at first; the diastole never lasts long enough for the ventricle to fill itself, the systole for the ventricle to empty itself. Then it is that digitalis lays its strong grasp upon the organ and bids it keep still; it gives it time to fill itself with blood, and power to propel this blood through the system. In this way it is that the tissues, being satisfied, cease

to urge the heart, that the lungs clear, and the dyspnoea abates.

Never as long as you live, gentlemen, give, in these cases of rapid pulse with cardiac weakness, aconite or veratrum viride. They are the very antagonists of digitalis, and when the latter does good they would act as true poisons.

Suppose we now consider the opposite extreme to dilatation,—namely, hypertrophy of the heart; where the organ heaves and throbs and the whole frame is shaken by the powerful impulse. Digitalis will very readily bring about in this heart a condition of spasm, and the patient may drop dead from syncope, depending upon a contracted heart. Thus digitalis, by stimulating a muscle already too powerful, does harm in simple hypertrophy of the heart. Here it is that veratrum viride and aconite are of service. Veratrum viride, whilst stimulating slightly the inhibitory apparatus, weakens most decidedly the muscular force of the heart. Under its use the pulse grows weaker and smaller.

There is another disease of the heart not connected with valvular lesion, in which digitalis is of great service. I refer to the irritable heart. It is most frequently found in soldiers, and in persons subjected for a long time to muscular strains.

As an instance of this irritable heart occurring in civil life, I mention the following case which I recently saw. A robust young man was in training for a rowing-regatta on the river. After a while he began to lose his wind sooner than his companions; and at last he had to give up the exercise altogether, for he was hardly able to walk up-stairs without severe palpitations and distress about the heart.

Irritable heart is nearly always due to over-strain of the viscus, is generally associated with weakness, and usually tends towards the production of cardiac dilatation. It is, I suspect, in some measure dependent upon a loss of power in the cardiac inhibitory apparatus. For obvious reasons, then, in most cases of irritable heart digitalis is of the utmost service. In some instances, however, the tendency is towards hypertrophy, and not towards dilatation. Under such circumstances, veratrum viride, not digitalis, is indicated.

In valvular disease with dilatation there always is weakness of the heart. Here the effect of digitalis is not so marked as in simple dilatation; but still, by regulating the heart's action, it probably diminishes the leakage of blood, and, by giving strength to the muscle, makes up to a certain extent for the deficiency.

Some of you may have seen me prescribe digitalis in cases of hypertrophy with valvular disease, and you may think that I contradict myself; but it is not so. The mere existence or non-existence of hypertrophy in a case of valvular disease is no criterion for the administration of the drug. The point to be decided is whether there be or be not *relative* hypertrophy; whether the increase in the strength of the cardiac muscle has or has not been proportional to the increase in the work required of it. To make this clearer, let us suppose that the healthy heart has to exert a force equal to 100 to pump the blood through the system. When there

is a leakage, the amount of work being increased, the amount of force needed will also be much greater. Suppose that the amount of work needed of the diseased heart then equals 200. It may be that hypertrophy shall occur under these circumstances to such an extent as to double the cardiac power; then all will be well: double work and double power will mutually balance each other. If, however, the increase of power shall fall short, amounting only, let us suppose, to 150, the organ is really in the condition of dilated heart. It is not the amount of power in the muscle, but the proportion of power to the demand, that is the question. A heart may be absolutely hypertrophied, but relatively dilated. Hence it is that the great question for the therapist is not to know which valve is diseased, but whether there is force enough for the demand. This is the criterion that must guide you in the administration of digitalis.

Practically, I believe the minute diagnosis of the exact character of the valvular lesion is often not important, and the question as to the availability of digitalis may be determined by studying the condition of the system. If the heart cannot pump the blood with sufficient power, of course the arterial system will be comparatively empty, whilst the veins will be full. Imagine the mitral valve to be eroded; at each contraction of the left ventricle there is a certain amount of blood thrown back into the auricle; this becomes distended, and cannot empty itself properly; the pulmonary veins opening into the auricle become engorged, and fail to carry the aerated blood away from the lungs. These become congested, so that the right heart, whose business it is to pump venous blood into the lungs, fails to do so properly, becomes distended, and prevents the unloading of the venous system through the two venæ cavæ; as a consequence of this general venous engorgement, œdema and dropsy come on. Almost always when you have venous congestions and dropsies the heart is weak; and you may set it down as a practical rule, with exceedingly few if any exceptions, that cardiac general venous congestions and dropsies call for digitalis.

In concluding this lecture, I call attention to the man before you as illustrative of the value of digitalis in giving temporary relief in cases of the most desperate and hopeless character. You will also notice the fact that in my treatment I have been guided by the general symptoms rather than by the cardiac lesion. Owing to the irregular and feeble action of the heart, the indistinctness of the murmurs, and the fact that auscultation distresses the patient exceedingly, I have been unable to make a positive, accurate diagnosis; in fact, at my first visits the condition of the patient was such that I did not even attempt a cardiac examination.

George R., æt. 43, German; shoemaker; admitted Oct. 3, 1874, into the house, complaining of nothing but dyspnoea, with which he had been suddenly attacked a month before, whilst working in a damp cellar. The dyspnoea was very great; the urine albuminous; the abdomen very hard and tender. There were two marked lateral areas of dulness, which presented distinctly the outlines of the liver and spleen, the edge of

the liver-dulness extending to within one inch of the crest of the ilium. There was some œdema of the feet. All these various evidences of damming back of the blood in the abdominal organs betrayed an intense cardiac obstruction. On the morning of the 6th of October the patient's pulse was 112, very nearly what it had been since admission, and he had passed only eighteen ounces of urine in the last twenty-four hours. He was then ordered fʒss of infusion of digitalis every three hours. To-day, the 10th of October, the shortness of breath is better, and he eats better, because the congestion of the stomach has been relieved. We must expect to find also a similar relief in the other abdominal organs. On percussion, the liver-edge is found two inches higher up than at the last measurement. The enlargement of the spleen has almost disappeared. The pulse, which was exceedingly weak, has become large and hard, and does not reach above 100. The congestion of the kidneys has been much relieved: we find that he now passes thirty-six ounces of urine in the twenty-four hours.

This man, then, has been very much improved, and yet we do not know what is the matter with his heart. The presence of so much portal congestion would seem to point towards the existence of disease of the right heart.

At a future lecture, gentlemen, I shall point out more in detail how digitalis is of value in especial cardiac valvular diseases, and how it is sometimes absolutely curative, and shall also speak of its danger and mode of administration.

ORIGINAL COMMUNICATIONS.

SCLEROSIS OF THE SPINAL CORD, WITH ATROPHY OF THE MOTOR CELLS IN THE ANTERIOR HORNS OF THE GRAY SUBSTANCE.

Read before the Pathological Society of Philadelphia

BY R. M. BERTOLET, M.D.

THE first series of specimens exhibited under the microscopes are transverse cuts of the spinal cord of an ordinary case of locomotor ataxy. The clinical records of the case are preserved by Dr. Pepper.

The alterations that have occurred in this cord have been limited chiefly to the posterior columns, giving rise to such decided gray degeneration in this section as to be distinctly visible to the naked eye; the translucent wedge-shaped segments, extending from without inwards, along both sides of the posterior fissure and cornu, penetrate up to the commissure. Here, microscopically, all the medullated nerve-fibres have disappeared, their places being taken up by anastomosing bands of fibrillated connective tissue: in other words, there has been an active proliferation of the neuroglia, in consequence of which the nerve-fibres have gone under; numerous corpora amylacea being the only traces indicative of their former existence. Here and there an axis-cylinder can still be detected. This sclerosis or gray degeneration of the posterior

columns is traceable from the cauda equina up through the entire length of the cord: unfortunately, the medulla and brain of this interesting case were ruined by being placed in an improper hardening solution. This gray degeneration of the white substance does not extend into the lateral columns, nor is there any decided lesion discernible in the gray substance proper, beyond the too homogeneous appearance of the stroma. The multipolar cells do not appear smaller than in the normal cord; no appreciable alteration is found in them; certainly their number is not diminished, nor is there any diminution of the size of the anterior cornu itself.

FIG. 1.

Transverse cut through the lumbar enlargement of the spinal cord.—Case of locomotor ataxy.

S S, the sclerosed posterior columns.

P C, posterior horns.

A C, anterior horns.

M C, motor cells of the anterior horns, which are grouped into E L, the external lateral, A E, antero-external, and I, the internal group.

My object in presenting these sections and the drawings of this typical case of progressive locomotor ataxy is to contrast them with the lesions found in the cord of a well-marked case of infantile spinal paralysis.

In the second set of specimens the microscopic sections also reveal the presence of extensive sclerosis of the posterior columns, showing the same exuberant development of connective-tissue fibres; in addition, there are seen disseminated in the anterior and lateral columns small isolated patches where a like indurative process is being developed,—*scélrose en plaques*. But by far the most interesting changes are those that have taken place in the anterior cornua of the gray matter (*vide* Fig. 2).

With a low power scarcely any of the large multipolar nerve-cells, ordinarily as thickly strewn in the anterior horns as the leaves in Vallombrosa, can be seen; while the lesser groups of these cells situated in the posterior horns, being more deeply stained by the carmine, appear in striking contrast with the surrounding tissues. A higher objective also fails to reveal most of the nerve-cells of the anterior cornua, which are conveniently, though not strictly, classified in three groups: 1, a large

external lateral group; 2, a small antero-external group; and, 3, a smaller internal group.

In these specimens it will be seen that the first group of motor cells has nearly disappeared, their places being occupied by a dense fibrillated mass, packed with inflammatory corpuscles; while in the second group but few of the motor cells remain. These are shorn of their long process, their nuclei and nucleoli being concealed by coarse granular pigment-matter, and their edges more or less corrugated: in short, they are seen in the various stages of atrophic changes. The smallest and internal group of these cells alone remains unaffected, the caudal prolongations and nuclei being clearly visible.

It may also be observed that several enormously dilated vessels are seen coursing in the gray matter of the anterior cornua.

FIG. 2.

Transverse cut of spinal cord through the lumbar enlargement.—Case of infantile spinal paralysis. There exists marked sclerosis of the posterior and anterior columns; not represented in the drawing. Great diminution in the size and number of the nerve-cells will be observed at E L and A E, the external and antero-lateral groups, while I, the internal group, remains unaltered. V V represent large blood-vessels in the anterior horns.

These changes were most marked in the region of the lumbar enlargement, whence the cuts that are exhibited were obtained. Sections through the brachial enlargement left no doubt that the process had already ascended to this point.

Whether an actual diminution in the size of the anterior cornua has occurred from the atrophy of the nerve-cells is a matter not so readily determined, since both cornua are in this case affected in about the same degree. This diminution is, however, very apparent when only one limb is paralyzed, as in a case of infantile paralysis reported by Charcot,* and in another by Prof. Roth.† T. Thompson Dickson‡ also observed the same phenomenon in the spinal cord of a patient who had suffered amputation of the right leg fifteen years before death. Prevost and David§ found a like

§ Arch. de Physiol. Normal et Pathologique, Juillet et Septembre, 1874, planche 24.

appearance in the right horn in a case of muscular atrophy of the thenar eminence.

Were all other proofs wanting, the data alone obtained from these cases of unilateral fascicular sclerosis would be sufficient to establish beyond all controversy the functions of the large multipolar cells of the anterior horns.

The entire length and thickness of all the white fasciculi may be so far involved in this process of sclerosis that not a single nerve-fibre with its axis-cylinder can be found, and yet the muscles do not suffer directly in their nutrition so long as the nerve-cells maintain their integrity.

It is a fact now generally recognized that the lesions of progressive locomotor ataxy, although most frequently characterized by sclerosis of the posterior columns, as in the typical case above, may at times have their seat in the lateral or anterior columns. Sooner or later the slow chronic irritative processes extend towards the gray axis of the cord and consecutively involve the anterior nerve-cells, causing them to atrophy and disappear in the contracting horns. It is then that the locomotor ataxy becomes complicated with progressive muscular atrophy. Cases illustrative of this point are given by MM. Pierret* and Charcot,† and others. This consecutive involvement of the anterior horns in Duchenne's disease is stated to occur in about one-eleventh of the number of cases.

In infantile spinal paralysis, on the other hand, the development or extension of the sclerosis to the anterior horns has lately been frequently observed. Through the kindness of Drs. Parry and Jenks, I have been enabled in three cases of infantile spinal paralysis to convince myself of the existence of the most profound alterations in a great number of the motor cells, and disappearance of others. Fig. 2 is taken from one of these cases.

Remarks.—Whenever we have superadded to the symptoms of spinal paralysis those of muscular atrophy, be the case one of paralysis in the adult or infant, we may, with the greatest degree of probability, expect to find alterations in the motor cells, since there is not a single well-authenticated case on record showing muscular atrophy as a result of the spinal lesion, where the motor cells have preserved their integrity. In these cases the muscular atrophy is unquestionably induced not by a primary affection in the muscles themselves, but is consecutive to the myelitis,—the evidences of myositis and fatty degeneration of the muscular fibres sometimes observed being therefore of secondary importance, and perhaps altogether accidental.

There are still many conflicting opinions held by different pathologists as to whether the lesions in the motor cells are primary or secondary to the inflammation of the surrounding tissues. Roth‡ is inclined to accept the latter theory in all cases, and this propagation of the inflammatory process along

the neuroglia to the anterior horns with the secondary involvement of the nerve-cells cannot be denied to occur in certain cases of central myelitis, spinal pachymeningitis, and tumors of the cord. Charcot,§ on the other hand, regards the lesions of the motor cells as primary in typical muscular atrophy, in infantile spinal paralysis, and in the spinal paralysis of the adult. The exact localization and limitation of the lesions in certain cellular groups is certainly a very strong argument in favor of their being affected *ab initio*. A very interesting case has recently been published|| where congenital atrophy and loss of power in all the muscles of the right thenar eminence were attended with a decided diminution in the size of the right anterior horn, and disappearance of its lateral motor cells. The lesion was most pronounced in the region of the seventh cervical nerve, not extending beyond the sixth and eighth; the white substance presented no appreciable alterations. The constantly increasing number of such cases where the alterations are seen confined to the anterior horns, leads us to believe that the nerve-cells are often the primary seat of the irritative process; although in each of the three cases of infantile paralysis examined there was found sclerosis of the white substance as well as in the gray axis.

The clinical histories of these cases of spinal sclerosis, even when the motor cells are involved, as manifested by the progressive muscular atrophy, generally show a very protracted affection, seldom in itself fatal unless the nerve-cells of the nucleus of the hypoglossal and of the spinal nerves are also involved at the same time as those of the brachial enlargement; then a fatal termination is prematurely induced, the symptoms of glosso-labial paralysis being superadded to the ordinary disturbance of the muscular atrophy.

It was formerly asserted that sclerosis of the lateral columns in itself is sometimes accompanied by general muscular atrophy; but later researches by the eminent neural pathologist Charcot¶ show that this is not the case unless the process has extended to the anterior horns. In a newly-described form of muscular atrophy resulting from this lateral amyotrophic sclerosis, the author, in the paper just referred to, draws attention to the predominance of the atrophy in the upper extremities, while it is at minimum in the legs, amounting to a mere simple paralysis. The arms in this affection, in spite of the paresis and rigidity, still are capable of performing certain movements, but with a trembling motion, which recalls to mind the shaking palsy observed in *sclérose en plaques*. In the few cases so far observed, a relatively short period, seldom extending beyond three years, elapsed before a fatal termination. The existence of this peculiar form of muscular atrophy, affecting uniformly all the muscles of the limb, needs further confirmatory observation.

ON PIGMENT-FLAKES, PIGMENTARY PARTICLES, AND PIGMENT-SCALES.

BY JOSEPH G. RICHARDSON, M.D.,

Microscopist to the Pennsylvania Hospital.

THE present paper is designed to direct attention to what I conceive to be an egregious error, by which several microscopists of acknowledged ability have been ensnared,—namely, a belief in the importance of the “pigment-cells” or “scales” described by Frerichs, of Berlin, as occurring in blood;* of similar bodies found by Drs. Meigs and Pepper, of this city, under like circumstances;† and of the “pigmentary particles” or “celloids” figured by Dr. William Roberts, of Manchester, England;‡ all of which I assert to be simply and solely *accumulations of dirt* (especially the remains of red blood-corpuscles) in the little excavations on slides in ordinary use.

Such an accusation as this will, no doubt, at first excite astonishment or even ridicule, but of course no sane man would dare to bring forward a charge of this kind without strong evidence in its favor. This evidence I ask each one of my readers to furnish me after trying this simple experiment:

Examine an ordinary plate-glass slide microscopically for *dirt-pits* containing brownish-red matter which may be oxide of iron, or, if the slide has been long in use, old red corpuscles. If there are none already filled up with “pigment,” rub in faithfully a little blood, by which means you can sometimes fill the shallow cavities with the débris of the red disks, and so imitate quickly the effect ordinarily produced in a gradual manner by frequently wiping small quantities of blood over the glass. Lastly, clean off the slide perfectly bright (so as to be sure you leave nothing but artificial *sells* upon it), and examine with a power of 250 diameters.

The bodies you probably find are accurately described by Dr. Roberts as follows:§ “Pigmentary particles; these objects deserve a passing notice from the fact that they are frequent, almost constant, if not absolutely constant, objects in urinary deposits, and have not hitherto been described. . . . They never exist in such quantity as to form the entire (*sic*) of a visible urinary sediment; they are only to be recognized by the microscope. They appear especially under two conditions—namely, as free amorphous particles and cell-like bodies (or celloids). . . . The cell-like particles have a peculiar appearance, very difficult to explain. They never present an unmistakably cellular character; they appear flat, never spherical. Their outline is generally an oblique ovoid. Within this outline, which is generally of exceeding delicacy and of perfect definition, lie masses of red or orange pigment, exactly resembling the free amorphous particles already described.”

Frerichs, after pointing out similar objects, says||

that accurate diagnosis can be made in malarial fever by examining the blood for them, since a few drops “are sufficient to determine the presence or absence of large quantities of pigment.”

Drs. Meigs and Pepper report finding pigment-particles in the blood of eighty-nine patients; but later these acute observers seem to have had shrewd misgivings respecting their importance, although without feeling satisfied as to their real origin.

My own suspicions were excited years ago by Frerichs’s pigment-scales, and experiments on hundreds of specimens of blood from malarial and other cases convinced me of their delusive character.

Very recently, Dr. James Tyson, of this city, whilst examining in committee some ovarian fluid, pointed out to me several of Roberts’s pigment-flakes, and said he had prepared drawings of these bodies for his forthcoming work. His statement naturally led me to a careful and prolonged study of the objects in question, and this in turn forced upon me the conviction above expressed.

Excluding carbon-particles (from the air), I attribute the peculiar shape of pigment-flakes which Roberts finds so “very difficult to explain” (admirably shown by Dr. Tyson in his plate), to the conchoidal figure of the minute chipped-out cavities in plate-glass; which little pits have, indeed, proved veritable pitfalls to unwary travellers over the microscopic field. These same shallow, shell-like excavations before being filled up with dirt are, probably, Frerichs’s “coagula of a hyaline character, which resemble in form” (as they have a perfect right to do) the pigment-flakes, and are also Roberts’s “bluish mother-of-pearl” celloids.

Dr. Roberts concludes, “I have been in the habit of noticing these objects for many years, and have regarded them as derivatives of hæmatin, but how they come to assume their peculiar forms I cannot conjecture.” With him, I believe them to be “derivatives of hæmatin,” but only by the *rubbing process* detailed above; and I trust that my “conjecture” as to how these hæmatin-flakes “come to assume their peculiar forms” will be satisfactory.

It seems almost incredible that the recorded appearance of these “flakes” in such various and inconsistent localities—viz., in blood, urine, the brain, in tumors, and even in the breath—has hitherto aroused no suspicion of their true nature; and it is only when we remember how few investigators have minds achromatic enough to enable them to see objective facts without subjective coloring, that we can offer a plausible explanation of this remarkable phenomenon. Does not the delusion which, if I am correct, has thus entangled several eminent observers, form one of the most curious episodes in the history of medical microscopy? and should it not serve as a warning to future generations of students?

Nevertheless, being always open to conviction, I hereby challenge any devout believer in pigment-flakes to bring me an honest specimen of urine, or blood from any ordinary case of disease, in which can be demonstrated either pigment-flakes, pigmentary particles, or pigment-scales.

IS CENTRAL PARALYSIS ONE OF THE TOXICAL EFFECTS OF THE SULPHATE OF ZINC?

BY B. F. POPE,

Assistant-Surgeon U.S.A.

MARTHA H., colored, æt. 30, a very fat, large-framed, full-blooded, and apparently healthy woman, complained to me on the 1st of July, 1874, that she had suddenly and entirely lost the use of her left hand and arm. She said that she had received no injury of either head or spine; and, furthermore, she had no recollection of headache, vertigo, or nausea prior to her attack.

Beyond this isolated fact of the loss of motor power, and a slight tactile insensibility, I could find no correlative symptoms during the first three days of her illness.

For various reasons, I was in the beginning somewhat inclined to suspect her of malingering, especially as the electro-muscular contractility was not impaired. On the fourth day, however, there was dragging of the left leg, immobility of the left facial muscles, and a dextral curvature of the tongue on its protrusion, with some thickness in speech.

In stooping, her arm dropped forward, and in walking, which she accomplished clumsily and with effort, it swung helplessly at her side.

I considered this to be an assemblage of symptoms that could hardly have been feigned by a person of her limited intelligence and power of mimicry. So I was obliged to relinquish the idea. As stated, the *cause* of her attack is apparently without explanation, save that it may be found in the following circumstance.

One week before, she had called upon me for relief from a severe and rather protracted attack of gonorrhœa. For this I prescribed an intra-vaginal injection of a solution of the sulphate of zinc,—five grains to each ounce,—to be administered on retiring for the night. She continued its use seven days; her gonorrhœa ceased one day before her paralysis appeared, and did not return again. Now, whether this sudden and unaccountable paralysis was due to the toxic effect of the sulphate of zinc, or to a suppression of her gonorrhœal discharge, or to neither, is a question of considerable moment; and for the purpose of eliciting other experience than my own I would make inquiry of some of your numerous readers for any similar cases that may have occurred within their knowledge.

The subsequent history of Martha H. is without interest, as her recovery took place within six weeks, under the tri-weekly application of both general and localized faradization. At this date (October 17, 1874) her cure is apparently perfect.

FORT STOCKTON, TEXAS.

RUPTURE OF THE SPLEEN (*British Medical Journal*, Sept. 26, 1874).—A lady aged 35, who had been subject to dyspepsia, and had suffered greatly from gastric pain due to an irritable stomach, died after a very short illness. The autopsy revealed an idiopathic rupture of the spleen, no symptoms of which had been detected during life.

NOTES OF HOSPITAL PRACTICE.

BELLEVUE HOSPITAL, NEW YORK.

CLINICAL SERVICE OF DR. ALFRED L. LOOMIS,

Professor of Pathology and Practice of Medicine at the University of the City of New York, Medical Department.

RHEUMATOID ARTHRITIS; HEMOPTYSIS.

PROF. LOOMIS delivered a clinic as above, on Tuesday, October 20. He appears to be very popular with the students and others, and always draws a good attendance. His lectures partake rather of a conversational character. Two or more students of the advanced class are called upon to assist in studying the disease, in making the diagnosis, and in suggesting a line of treatment. It was so in this case, which will account for the peculiar manner in which some portions of the following are presented. He said,—

Gentlemen: We have this afternoon two interesting cases.

Case I.—Here is a woman whom I present especially to show you the condition of affairs described to you already in my lectures. I told you that there were deformities occurring in connection with chronic articular rheumatism. It is not necessary for us to make a diagnosis in this case. You see readily the position which the lower limbs have assumed: they are perfectly rigid, ankylosed at the joints, and drawn up at an angle. The band which you see between the knees is placed there in order to prevent sores from forming by pressure. You see the same contracted condition in the hand. You remember that I said that this form of rheumatism commences in the larger joints, involving secondarily the smaller joints; that this is a hopeless form of rheumatism from the commencement; that patients of this class go on from bad to worse. Each time that they have an acute or a subacute attack they are left in a worse condition than they were at the former attack, until they become drawn out of shape, as this woman is, and are put in a position in which they have to be cared for either by friends or in hospitals. I know of no treatment that has any power even to arrest the progress of the disease. I know of nothing that gives them even temporary relief. When I am called to a case like this in private practice, I simply make the diagnosis and give the prognosis, and say to the friends of the patient, "I am powerless to relieve." It is said by writers that the afflicted go to certain springs in carriages, and, after partaking of the waters for a longer or shorter period, walk away. But such relief, so far as I have seen it, is only for a short time: they are very soon back again. Other than the deformity, this woman's general health is pretty good. Such cases generally have good bodily health; intellect is perfectly clear; they suffer more or less pain, and, as a rule, they become opium-eaters, for which I don't blame them!

Case II.—This young woman, aged 23 years, states that she is always sick, and that seven years ago she was confined to bed with throwing off of blood. Q. (to patient)—Do you remember how that throwing off of blood occurred? A.—I coughed it off. Q.—Did you cough before the blood made its appearance? A.—Yes. Q.—How long? A.—Soon after I had an attack of the smallpox. Q.—When did you have the smallpox? A.—When I was six years old. Q.—How many hemorrhages have you had? A.—A good many. Q.—A dozen or two each year? A.—Yes; I cannot remember how many a year. Q.—How much is the greatest in amount which you ever spat up? A.—A basinful. Q.—What was the cause of the hemorrhage?—what brought it on? A.—Pain in the left side. I never lost much flesh before, but this time I have. I

began to lose flesh before I came in here. I have been in here three months. *Q.* (to the *interne*)—How many hemorrhages has she had since she came in the hospital? *A.*—So many that I don't remember: it is a clear hemorrhage; there are streaks of blood mixed with the mucus. The last hemorrhage was three or four days ago. She is unwell regularly every month; never had any trouble.

Now let me tell you (observed the professor) that nine cases out of ten of hæmoptysis which you meet with come from the bronchial mucous membrane. It does not come from the lung-substance so often as one may imagine. Now, there are two different conditions of bronchial hemorrhage. What are they? 1, distention of the capillaries of the bronchial mucous membrane; 2, weakness of the walls of these capillaries. In nine cases out of ten this bronchial hemorrhage is due to an hereditary or acquired weakness of the capillary blood-vessels of the mucous membrane of the bronchial tubes. In a large proportion of these cases, very fortunately, the patient seldom or never dies. Many persons may have perhaps forty or fifty hemorrhages before the age of twenty-four or twenty-five, then they cease, and the person may go on and live to an old age. Now, in these cases there is almost always an hereditary tendency to bronchial hemorrhage. I will ask this girl the question whether any of her family have bled like her. *A.*—Yes, on my father's side. *Q.*—Did your father have hemorrhage? *A.*—Yes.

You will find always that a certain proportion of hemorrhages occur as a result of acquired weakness of the capillaries. For instance, here is a patient developing a phthisical condition, and that condition is marked by hemorrhage, and these hemorrhages are due to weakness in the capillary vessels. That is a point I insist upon very much. You say it is a very bad sign for a man to have hemorrhage: it is a sign that he will probably develop phthisis. Now, he may or he may not: it depends upon how he manages himself. If his hemorrhage occurs after exercise, he is not so badly off as when it occurs without exercise. A man lifts to excess, and immediately after has a bronchial hemorrhage, which lasts him for some time, and he gets well and never has another. Whether hemorrhage occurs in connection with the external manifestations of phthisis or not (the person may not present the appearances of phthisis; they occur in persons sometimes in the full condition of health), it indicates that it is important that the whole nutrition of the individual should be changed. The whole habit of life must be changed in order that the nutrition may be increased, so that a repetition of hemorrhage may not take place.

Q. (to the students)—Is there any particular danger from bronchial hemorrhage? I mean any immediate danger? *A.* (by the students)—No. You may tell the patient (said the professor) positively that he will not die from bronchial hemorrhage unless the shock to the system is great. He will get better from the hemorrhage; but at the same time it tells you positively that the man is in danger from the development of phthisis. He may not, however, develop phthisis from this single hemorrhage. *Q.*—What, then, is the danger? *A.*—He may die from anæmia. *Q.*—Yes? *A.*—You may have inflammation of the lungs. *Dr. L.*—I don't think there is much danger from that; but you may have an excited condition of the bronchial tubes,—bronchitis. A condition of hyperæmia of the bronchiæ may have preceded the hemorrhage; a bronchitis may follow immediately after the occurrence of the hemorrhage. When the hemorrhage comes on under these circumstances, it is much more dangerous than without exposure.

Now the question occurs, What means would you apply? *A.*—Apply styptics. *Dr. L.*—Yes, styptics, rest, and nutrition. They even recommend ice to be applied

to the chest. If a man catches a hemorrhage in Germany, he will be packed in ice as sure as fate! And that they will develop broncho-pneumonia is about as certain as that the patient is packed in ice. Then these hemorrhages are not immediately dangerous; and the most important element in the treatment, so far as controlling the hemorrhage is concerned, is—what? Keep still; rest,—that is the whole thing. Put the patient to bed, and let him lie there. You need not give styptics; you need not put him in ice. If you keep him still, and if the family and friends do not talk to him and excite him, he may get better. The capillaries are in the same condition as the lungs when ruptured. Rest, then, is the principal thing; nutrition may be added afterwards, and that is about all. But suppose he has a cough, and the blood follows: give opium in quantity sufficient to quiet the cough if he does not remain quiet without it. Is there anything else that you can do? *A.*—That is enough. *Dr. L.*—Yes, that is enough; wait. He will get along ten times better than if you throw into the stomach a dozen styptics. These are points which I wish to impress upon you: they are practical. There is more harm than a little done by the bad management of bronchial hemorrhage, and frequently the bad management is a cause of the development of phthisis.

You may have bronchial hemorrhage from other causes than exercise. A person goes up in a high latitude. If this class should go up into a high latitude, about one-third of the number would have bronchial hemorrhage simply from atmospheric changes. Those persons have a greater weakness of the capillary vessels than others, yet they may never develop phthisis.

Again, certain irritations will give rise to bronchial hemorrhages, like the irritation of gases or dust. A man has a cavity in his lungs. He is never free from danger of profuse hemorrhage when he coughs violently. Under these circumstances, hemorrhage is always dangerous. The cavity in the lungs increases; and the walls of the vessels of considerable size become involved in the ulceration. When hemorrhage occurs in connection with a cavity, it shows that the vessels are in a gangrenous condition. It is not the ordinary phthisical process, but a gangrenous condition. In this condition, the danger is that the patient will bleed so much that he will die from the loss of blood.

This woman has phthisis developed on the left apex; has had hemorrhage for seven years, without any phthisical development until within the last year or two.

W.

TRANSLATIONS.

INVESTIGATIONS ON THE INTESTINAL JUICE.—M. Leven communicated to the Société de Biologie, at a recent sitting, the results of his studies upon the intestinal juice.

This is not, as has been believed by many authors, an alkaline liquid. M. Leven has, on the contrary, always found it acid; when, as was done by M. Moreau, the intestinal juice is collected in an isolated pouch of which the nerves have been cut, a liquid is produced which is derived from the vessels, and which is not the true succus entericus.

The acidity of the intestinal juice is not produced, as Blondlot and Lehmann have supposed, by the formation of acids derived from saccharine and starchy matters.

M. Leven demonstrates this by his experiments upon dogs. When a dog is given seventy-five grains of sugar, absorption is complete in five minutes; the sugar cannot in that time become decomposed in order to produce acidity.

If a dog is given two and a half ounces of starch, sugar is found at the end of five hours in the intestines and in the blood; but the intestinal liquid remains neutral, since the sugar and the starch are not the cause of acidity. Finally, the intestinal juice is acid when it is removed from the intestine, and an infusion of intestine in tepid water gives an acid liquid.

An observation of Busch, who nourished a woman suffering from fistula of the small intestine by passing the food into the lower portion, is a proof of the digestive activity of the intestinal juice. This proceeds from the glands of Lieberkühn, the glands of Brunner, and perhaps from those of Peyer. In every case the intestinal juice may take the place of the gastric and the pancreatic juices, or at least furnish phenomena of digestion similar to those produced by the latter.

A. V. H.

VEGETATIONS OF THE VULVA.—Dr. Dubrueil has frequently had occasion at the Hôpital de Lourcine to combat vegetations of the vulva. This affection is quite rare in civil practice. It has nothing of a specific nature about it, since it may be met with among virgins, or may be brought about by gestation.

In the latter case no treatment is of use, at least until the termination of pregnancy. In other cases it is necessary to interfere, since the progressive increase in the size of these morbid productions is indefinite.

When called to a case in good time, while the vegetations are but little developed, cauterization with chloride of antimony or the acid nitrate of mercury, or excision followed by cauterization of the wounds with nitrate of silver, may be successfully employed.

It is otherwise, however, if the disease has progressed for a long time. In this case one is confronted by enormous fungosities, the pedicle of which is often difficult to make out. By what means shall they be attacked? The disease is too wide-spread for caustics to be thought of. The use of the *écraseur* may give rise to accidents. It often gives good results in the anal regions, since there the skin is adherent to the subjacent parts. About the vulva, where the skin is more mobile, the risk is run either of including a part of the labium majus in the grasp of the *écraseur*, or of allowing some of the vegetations to escape. Cutting-instruments may occasion hemorrhage difficult to suppress.

The galvano-caustic knife possesses, at least to a certain degree, the same inconveniences as the *écraseur*. This instrument cuts badly; the operator in using it is obliged to exert a certain degree of pressure on the tissues which he wishes to divide, and if this pressure is not very exactly adjusted there is danger of going too deeply or of leaving some of the morbid tissue behind. M. Dubrueil seeks to avoid all these inconveniences by combining the action of the cutting-instrument with that of the galvano-cautery, reducing the latter to the place of a hæmostatic. He snips off the vegetations with scissors, either by a single cut at their base, or by careful progressive movements of this instrument, if there is any doubt as to the limits of the disease.

Arriving at the tissues of the labium majus, he brings the galvano-cautery to the surface of the wound, and by this means controls the hemorrhage without entirely arresting it.

By this operation the patient is relieved at a single sitting; or, if small portions of the vegetations have escaped, a slight cauterization suffices to bring about a cure. It is best to follow the operation by dressings wet with a solution of perchloride of iron, or even of a tampon of charpie soaked in this liquid and allowed to remain in contact with the tissues for half an hour. It is true that these dressings are painful, but they are very efficacious in preventing relapses.—*L'Abeille Méd.*, Oct. 19, 1874.

A. V. H.

INFLUENCE OF TEA AND COFFEE ON THE EXCRETION OF UREA.—Brown-Séquard's *Archives*, July and September, 1874, contains a communication by Dr. E. Roux, comprising the results of a number of experiments performed on himself. His object was to ascertain the influence exercised upon the excretion of urea by the use of tea and coffee. His conclusions are as follows:

1. The quantities of urea, uric acid, chlorine, and phosphoric acid, excreted in twenty-four hours with the urine, are quite constant under the same conditions of regimen and alimentation.

2. The relation of urea to chlorine is constant when the quantity of urine eliminated is restricted within certain limits.

3. The ingestion of a large quantity of water does not augment the amount of urea, uric acid, or phosphoric acid excreted in twenty-four hours.

4. Acidity is notably diminished by the ingestion of large quantities of water.

5. The amount of chlorine eliminated in twenty-four hours is in proportion to the urine passed, and consequently to the fluids ingested.

6. In a person unaccustomed to the use of coffee, ingestion of this article augments all the solid matters of the urine.

7. This augmentation affects in particular the urea and chlorine. The relative proportion of chlorine to urea remains unchanged.

8. If coffee is used continuously, a certain toleration for it is established, its effects being less marked, and the excretion of urea and of chlorine becoming normal.

9. These conclusions are applicable as well to tea; only in the case of ingestion of tea the effects are less marked and more temporary, probably because the doses are smaller.

A. V. H.

THERAPEUTIC NOTES.

SUPPOSITORIES OF CHLORAL.—

R Chloral, ℥iiss;
Ol. theobromæ, ℥iiss;
Cera alb., ℥vss.—M.

Ft. suppositor. No. vi.

R Ol. theobromæ, ℥v;
Cera alb., ℥iiss;
Glycerinæ, ℥iv;
Chloral., ℥iiss.—M.

Div. in suppositor. No. vi.

The chloral should be dissolved in the glycerin at a gentle heat, and the cacao butter and wax added subsequently.

These suppositories of chloral are recommended by Dr. Const. Paul in cancer of the uterus. His formula is—cacao butter 11 grammes, white wax 7 grammes, and chloral hydrate 6 grammes, to be divided into six suppositories.

ANTI-GASTRALGIC MIXTURE.—

R Tinct. castor., ℥ii;
Tinct. opii, ℥xxx;
Tinct. menth. pip., ℥xv.—M.

Sig.—Eight to ten drops from hour to hour, in a tablespoonful of sweetened water. Useful in the pains of cardialgia, also in flatulence, and in pain in the intestines.—*Dr. De Savignac, Gaz. Méd. de Paris*, September 5, 1874.

COD-LIVER OIL.—M. Guichard states that for many persons cod-liver oil can be sufficiently disguised by breaking up sardines in it. The person should first be taught to like sardines, then the oil of sardines, and then it is but a short step to cod-liver oil with sardines crumbled in it.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, NOVEMBER 14, 1874.

EDITORIAL.

PRIMITIVE SURGERY.

ACCORDING to a paper read by Dr. Prunières before the recent Prehistoric Congress at Stockholm, trephining was frequently practised during the prehistoric Stone Age. It is stated that the operating surgeons of that date, working with flint implements, scraped the bone, layer by layer, until the dura mater was exposed. Skulls both of children and adults, with the orifices in some instances partially cicatrized, have been found in abundance. The crania have been submitted to M. Broca, and we suppose there is no room for doubt as to the fact that the trephining was in many instances performed during life, although skulls were also discovered from which the circular pieces had apparently been removed after death. It has likewise been observed that the fragments of bone have been replaced in the skull before interment, apparently with the intent that the person should appear in the next world in his entirety.

M. Prunières is of the opinion that the operation was practised for medical purposes, to give exit to a real or imaginary disease, and also that insane persons and epileptics, the friends of the gods of the old beliefs, were especially the subjects of it, and that the pieces of removed bone were used as charms and amulets. Both M. Broca and M. Prunières think that they see in this practice the most ancient material proof of belief in another world, and that therefore even the primal man of the Stone Age was a religious animal.

AMERICAN SODA.—Five million nine hundred thousand dollars' worth of soda, it is stated, are yearly imported into the United States for use in the arts. Six hundred miles west of Omaha, and about forty miles north of the line of the Union Pacific Railroad, there is said to be an inexhaustible supply of the carbonate, in a much purer form than the crude imported ash. In one place there is a surface deposit many acres in extent, and six feet deep, whilst alkaline lakes and smaller deposits everywhere abound. It is stated that when the branch railroad is constructed to the deposit, the material can be placed in New York at about three-fifths the cost of the foreign article.

THE LONDON WOMEN'S COLLEGE.—The London Council has given the following evasive answer to Dr. Anstie's letter asking for recognition:

"That whilst they take no objection to the list of names submitted to them in the letter of the late Dr. Anstie as teachers in the proposed school, they are not prepared to imply a readiness to recognize a school which is incomplete and respecting which they have so little information."

LEADING ARTICLES.

THE PRESENT STATE OF TRANSFUSION.

II.

BEFORE going on to speak of animal transfusion, we may allude to the diversity of practice which obtains in relation to the use of arterial or venous blood. All possible permutations have been attempted; blood has been transferred from vein to vein, from artery to vein, and from artery to artery. Hüter, who proposed the latter method,* gives the following reasons in its favor: 1. The injected blood goes more slowly and regularly into the circulation than by venous transfusion. 2. If a bubble of air should remain in the syringe it would be absorbed in the blood-mass, while if a vein were injected the heart would be reached so much sooner that the danger would be greatly increased. We do not remember to have recently met with any discussion on this point. Most writers use one method or another without giving any reason therefor.

The recent revival of animal transfusion was inaugurated by Gesellius, of St. Petersburg, in 1873.† This investigator endeavored to disprove the generally accepted opinions: 1, that the blood of any given animal acts as a poison upon any other species or upon man; 2, that only defibrinated blood should be used for transfusion. Gesellius used the blood of dogs, lambs, and calves, and the transfusions were "immediate,"

* Deutsches Archiv für Klin. Med., Bd. xii. p. 1, 1871.

† Transfusion des Blutes. St. Petersburg and Leipsic.

silver canulæ being placed in the artery of the giver and the vein of the recipient and joined by a glass tube. In addition to the results of his own experiments, he adduced statistics to support his views, and combated vigorously Hüter's notion of arterial transfusion, maintaining that blood containing fibrin should be used, and that it should be transferred from the artery of the giver to the vein of the receiver.

The most striking portion of Gesellius's argument is that which relates to the advantages of animal blood for the practical use of transfusion. Hasse, of Nordhausen,* followed with a series of experiments in the same direction, including cases of phthisis, chlorosis, cachexia, carcinoma, and uterine hemorrhage, in which he used immediate transfusion of lamb's blood. Hasse's success, particularly in phthisis, led him to assert that "in direct arterial transfusion with lamb's blood an essential aid has been discovered in the treatment of this affection."

More recently, Drs. Fidler and Birch-Hirschfeld† have investigated the utility of transfusion with lamb's blood; but their conclusions are far from being so favorable as those of Gesellius and Hasse. In fact, during a discussion upon the subject before the Dresden Association, these physicians declared that they had been unable to derive any benefit whatever in tuberculous cases from such transfusion. So far to the contrary, that in many of their cases the condition of the patient was much worse subsequent to the operation.

Meantime, the German medical press teems with accounts of transfusions with lamb's blood under every variety of circumstances. Thurn‡ gives cases of amputation, catalepsy, carcinoma uteri, poisoning by carbonic acid, post-partum hemorrhage, phthisis, etc., with varying results; Brugelmann,§ cases of anæmia, and of various lung-affections; and Klingelhofer,|| of amputation and chronic bronchitis. The results of these investigations are in the highest degree contradictory, but for the most part may be said to tend to an unfavorable conclusion.

Turning from these clinical researches to those of a physiological character, we find the recent investigations of Landois, of Greifswald, possessing a high scientific value.

This physiologist mixed the blood of various mammals together, and also mingled the former with the blood of the frog, observing by the aid of the microscope the effect produced upon the corpuscles.

The pure serum of one species was also mixed with the blood of others, so that any action upon the latter might be more accurately observed. It was found that the blood-current, or, more properly, the serum, of certain species, exercised a decidedly solvent action upon

the corpuscles of others. This action varied greatly in different cases, the corpuscles of some animals being much more resistant than those of other species. Disintegration of the corpuscles, however, invariably resulted sooner or later, followed by a precipitation of fibrin. The fibrinous precipitate being derived from the stromata of the blood-globules themselves, previous defibrination would seem a matter of indifference, since the débris thus resulting would in any case be likely to give rise to clots in the vessels. Dr. Landois suggests that in rapid transfusions, when considerable quantities of foreign blood have been thrown into the veins of an animal whose blood-corpuscles are easily soluble, dyspnoea, convulsions, asphyxia, or even death, may result.

He believes concerning the destination of the transfused blood that a certain quantity is assimilated, while another portion passes off with the excretions, particularly the urine. When the transfusion is performed slowly and only a small quantity injected, the amount which finds its way into the urine is much less, and it may be supposed that more blood is assimilated. As to any assumption on the part of the injected corpuscles of their own peculiar physiological functions, Dr. Landois thinks this hardly worth consideration. He admits, however, that experiments with the blood of identical or closely-allied species are wanting.

Looking at these investigations as representing recent advances in our knowledge of transfusion, the question may be regarded as in a very unsettled condition. Excepting Landois and a few others, the various experimenters seemed carried away by the clinical idea, without due regard for the very imperfect physiological basis upon which it rests. Transfusion is well enough when we know exactly with what fluids we are dealing and what their mutual interactions may be; but in the present state of our knowledge, or rather ignorance, this is certainly not the case.

But while the practitioner called upon suddenly to treat a case of exhaustion from hemorrhage cannot stop to debate the comparative solubility of blood-corpuscles or to decide upon the relative value of mediate and immediate methods, yet these and the other points involved should be decided for him by the clinician, whose labors, it seems to us, should be based on the results of the physiologist.

Among the many questions relating to transfusion which seem to call for an early and satisfactory solution, the following suggest themselves as of paramount importance:

1. As to the admixture of the blood of different individuals of the human species. Do the blood-globules of the giver assume their physiological functions in the blood-current of the recipient, or are they dissolved?
2. In the latter case, does the dissolved portion supply pabulum to the organism? Does it alter the physical properties of the blood-current (specific gravity, etc.), or does it change the chemical constitution of the vital fluid of the recipient?
3. Do the stromata of the injected corpuscles remain

* Tagesblatt der 46en Versammlung Deutscher Naturforscher. Wiesbaden, Nov. 7, 1873.

† Deutsches Archiv für Klin. Med.

§ Ibid.

|| Ibid.

undissolved? and, if so, under what circumstances can the least formation of *débris* and fibrinous precipitation be attained?

4. If the injected blood acts merely in a mechanical manner, by changing the density of the recipient's blood, or chemically, in altering its reaction, etc., what effect would be produced by the substitution of injections of albuminous or saline solutions or artificial imitations of blood? Could not some artificial preparation be made use of which would produce the effect of blood while avoiding all danger from undissolved fibrin?

5. Any further investigations relative to transfusion with the blood of the lower animals should be preceded by experiments upon the comparative solubility of their blood-corpuscles in the blood-current of the human species. Such experiments might be based upon and complementary to the very scientific investigations of Landois.

The field of discovery here open is most promising, not only for the immediate gain to science, but for the ultimate results which may accrue to practical medicine when the operation of transfusion is placed upon a rational basis.

PROPOSED RECONSTRUCTION OF THE BRITISH ARMY MEDICAL DEPARTMENT.

THE altered system of war has naturally necessitated a reconstruction of armies in all their branches, but in none was this more imperative than in the medical department. More men were wounded in a single day during the Franco-Prussian war than in a year of the Peninsular campaign, and it is therefore a matter of pressing necessity that the best possible scheme of hospital organization should be at once devised and adopted.

In the old days, when wars were protracted, when the marching was slow, and months were passed in winter quarters, the badly-wounded cases were sent to the hospitals in the rear, while such as were able to be moved accompanied the army, and fared very well, except perhaps in a retreat or during a hurried advance.

The regimental hospital system then sufficed; but now probably even those officers who are most wedded to it would confess that, while it may meet the wants of soldiers in time of peace, it is totally inadequate to the wants of a modern army in active service, and that some method for forming an efficient and well-disciplined sanitary corps must be devised. The peculiar elasticity of our army organization, the extreme improbability of the United States being suddenly plunged into any war which should involve the employment of large land-armies, the general feverish desire to avoid national expense, and the wide-spread and not altogether foolish feeling that the "Yankee" will take care of himself in all emergencies, tend to prevent any rational consideration of the subject of army medical reform in this country. But in England it is different. Men are much

scarcer, and are probably more highly valued, in a military sense, there than with us. Certainly the country is liable almost at any time to be dragged into a general European war, and even to be called on to resist invasion. Army matters in England have therefore a vital interest for every one, and every branch of the service is looked after.

Accordingly, on the 1st of March, 1873, an army warrant appeared which removed medical officers from their regiments and placed them on a general staff list, thus breaking up old friendships and associations, and depriving them of their homes, and of the advantages of libraries, bands, etc., to which they had contributed. Many, too, had paid large sums for exchanges, which they lost, and, in place of being officers belonging to distinguished regiments, they found themselves without prestige or position, members of a medical staff corps, and liable to be sent to any part of the world at short notice. In compensation for these serious losses, nothing was granted except a change of title, by which an assistant-surgeon became a surgeon, and so on for the superior grades in the medical service.

The following reorganization has been proposed, as involving no expense to the country, restoring to the medical officers most of the regimental advantages which they have lost, and insuring the economy and unification which are needed for the reconstruction of the Department. The Army Medical and the Army Hospital Corps shall be amalgamated into a Royal Sanitary Corps, which shall take rank with the other scientific corps. The officers of this corps shall be permitted to wear the ordinary distinctions and badges of their rank on their uniforms, with such others as are special to the corps, but shall have no command, except over patients in hospitals, or over officers and men immediately attached to hospital establishments. Medical officers are to be completely separated from regiments, and when with them are to be attached as honorary members only, but for all duty purposes they are to be kept as long as possible with corps. When regiments are moved to new stations, their medical officer should accompany them, and after handing them over to the officers of the medical corps already there, who have had some experience of the diseases of the region, they should return to their former stations. Until experience has shown the method that is most appropriate to peace and war, the sick shall continue to be treated regimentally.

CORRESPONDENCE.

NEW YORK SOCIETIES.

NEW YORK, October 30, 1874.

AT a meeting of the New York Pathological Society, on the evening of October 28, Dr. Satterthwaite presented a tumor removed from a lady, aged 45, in the early part of the last summer. She was married twenty-three years ago, and has had three children. The first

child was an eight-months' child, which she nursed for three months, when it died. She was, however, requested by her physician to keep up the flow of milk. She used for this purpose a breast-pump. This instrument gave her great pain, which increased; and soon after, she struck her breast against a door. She nursed two children after that, and noticed that this breast—the right one—was somewhat larger than the other. About ten months before the third child was born, there was a discharge from the nipple. Some fifteen or sixteen years ago she noticed small lumps in the breast, which had grown greater until the time the breast was removed. The tumor was removed, and there has been no evidence of a recurrence. A cut was made in the tumor, and the difficulty can be traced directly into the milk-tubes. This growth, entering into the milk-duct, shows granular structures.

Dr. Erskine Mason presented a *ruptured bladder* from a boy about 11 years of age, and gave the following description of the case:

"He entered Roosevelt Hospital on the 8th of July. Six days before admission, he said he was kicked by one of the boys while playing at school. It gave him little pain, but for some hours afterwards he was unable to pass water. Later in the afternoon he was able to pass his water frequently, and apparently without trouble. Forty-eight hours after that he passed no urine, when a physician was called, who introduced a catheter and relieved him. During all this time there was comparatively no pain whatever. On the 10th of July he was running about the yard of the hospital. He was about that time placed on a bed to be thoroughly examined. Pressure upon the abdomen above the pubis produced no pain. Examination per rectum produced no pain. The only thing he complained of was that he could not pass his water, which was drawn off twice a day. On the 12th of July his urine was noticed to be bloody and offensive. He then commenced to have some pain above the pubis. He was placed in bed, and the bladder washed out. On the 19th of July he passed a few drops of water through the urethra. Everything went on rather favorably, apparently. He complained at times, however, of having a little pain over the pubis, and he eventually had cystitis, the urine being at times turbid and offensive, and sometimes dark brown. On the 20th of July his bladder was washed out about four o'clock in the afternoon. At five o'clock that same afternoon he was noticed to be reeling about, and shortly after he passed into a semi-comatose condition. The pupils were non-responsive to light. He remained in this condition about half an hour. On the 25th of July I found him suffering with pain above the pubis, and the house-surgeon had some difficulty in passing the catheter. He found an obstruction at the neck of the bladder. I never before suspected that he had rupture of the bladder, but I suspected it at that time. I passed my finger into the rectum, and I found that it had sloughed away beneath the bladder, and a swelling passed all along the ramus of the ischium. I instantly had the patient etherized, and as soon as I entered the bladder, bloody

urine flowed out. The bladder was before very much distended; it now collapsed at once. On introducing my finger into the bladder, I found a condition of things that I never met with before. I felt something in the bladder; what it was I could not tell. It was like a soft tumor. That operation was done at five o'clock on the 25th of July. At nine o'clock that evening the bladder began to be distended again. The patient suffered much. He was unable to void a drop of urine. The house-surgeon introduced a catheter, and relieved him. This condition of things continued until the 26th. I then put the patient under ether again, and made another examination, passing my finger, and pushing something before it, when the urine immediately flowed freely. Still the catheter had to be used three or four times a day. On the 28th of July a large quantity of pus discharged itself from the wound, and the patient felt considerably relieved. From that time up to the period of his death the urine flowed freely from the wound.

"On the 8th of August he was taken with diarrhœa, and succumbed on the 11th. A few days before death, he had cough and other symptoms of pleurisy.

"The autopsy was made on the following day. There was recent effusion over the right kidney, and there was an infiltration of pus. The left kidney was normal. The vesical mucous membrane was covered with pus. There was a large rupture on the posterior walls of the bladder. One of the torn edges projected into the cavity of the bladder. The rupture was in front of the neck. Now the condition of things was understood, and this explained why the urine did not flow from the bladder, and also why it flowed while using Thompson's dilator. It will be seen that when the finger is passed into the bladder the flap or torn edge lies directly over the urethral opening.

"Some two years ago I had a patient with a rupture of the bladder, and at that time I looked up the literature of the subject, and found that one case, referred to by Dr. Peaslee, lived forty-two days. My case lived forty-one days. He kept around for eighteen days.

"I feel, Mr. President, that if I had made a rectal examination at the time the patient entered the hospital I probably would have detected the real nature of the disease. There was no symptom to cause one to make such an examination."

Dr. J. Lewis Smith presented the thoracic organs of an infant who died at the age of about five and a half months. Its principal symptom was a *wheezing respiration*; the temperature was normal; the respiration somewhat accelerated, nearly 40; pulse 90.

Diagnosis.—An *enlarged gland pressing upon the bronchial tubes*. The child died of diarrhœa. At the post-mortem, the bronchial glands were enlarged and ulcerated. Tubercles scarcely visible in the lungs. When there is wheezing respiration, in the absence of pulmonary signs of disease in a child under two years of age, one of three things may be looked for: 1, a pharyngeal abscess; 2, a small abscess developed on

the mucous membrane of the larynx or trachea; 3, bronchial phthisis.

At a meeting of the Medico-Legal Society, held October 22, Prof. R. Ogden Doremus, M.D., delivered an address upon "The Duties of Members of the Medical and Legal Professions, Toxicologists, Pharmacutists, and County Officers, in Cases of Poisoning, and the Necessity for Proper Legislation on the Subject." He said it is a popular delusion that the stomach is the privileged and chosen organ for the reception of poison, and it is the organ submitted to the toxicologist for chemical test. But attention should be paid to the preservation of articles of diet and the various vessels used by or for the victim. When death has been caused by gas, unusual acuteness on the part of the chemist is required. The examination of the body of one killed by a volatile poison, such as hydrocyanic acid, ether, or chloroform, should be made only in the chemical laboratory; and, for his own part, he preferred that the intestines and not the stomach should be submitted to the tests.

Dr. Doremus closed by offering a resolution that a committee of five, consisting of two physicians, two lawyers, and one chemist, be appointed to consider the question as to what additional legislation should be secured in regard to poisoning and the sale of poisons; also as to the right of a coroner to engage the services of chemists and other experts when, in his discretion, the interests of the public demand their aid.

The resolution was passed unanimously, and the Society then went into election of officers for the ensuing year.

W.

REVIEWS AND BOOK NOTICES.

CLINICAL LECTURES ON DISEASES OF THE NERVOUS SYSTEM. By WILLIAM A. HAMMOND, M.D. Reported and edited by T. M. B. CROWELL, M.D. New York, D. Appleton & Co., 1874.

The judgment which is passed upon a book depends largely upon the standard in the judicial mind. If the present volume is to be taken simply as the expression of a course of ordinary clinical lectures to students, we say unhesitatingly that those lectures are mostly very good,—well considered, logically wrought out, and clearly expressed. If, however, the book claims to be more than this,—if it is meant to be one of those masterpieces of medical art that become classic, such as Trousseau's clinical lectures,—we express the conviction that it falls far below deserving such destiny. Very many of the cases have not been followed out, and do not afford the data for positive opinions. Some of the diagnoses seem to us to rest upon insufficient grounds, and we find very little that is strikingly novel, or that is even put in a strikingly original manner. The articles are unequal; some of them being much fresher than others. But the fault which, we suppose, will most affect the sale of the book is its incompleteness,—many nervous affections being scarcely touched upon, or altogether omitted. Notwithstanding these deficiencies, the practitioner who is not in possession of or acquainted with Dr. Hammond's general treatise, or some other standard authority, will find much

pleasant and instructive reading in the present volume.

THE BREATH, AND THE DISEASES WHICH GIVE IT A FETID ODOR. By JOHN W. HOWE, M.D. New York, D. Appleton & Co., 1874.

This little brochure contains about one hundred pages of large, wide-leaded type, yet affords space enough in which to say all that need be said upon the subject of which it treats. "Bad breath" is often a most unmitigated nuisance, not so much, it may be, to its owner as to his friends. To any one suffering from this affliction either in his own person or in that of his intimate acquaintances we can commend this volume as containing all that is known concerning the subject, set forth in a pleasant style. Along with a tooth-brush and a *carte blanche* at the dentist's, it would form a most suggestive and, it might be, invaluable Christmas-gift,—as a matter of course, appropriate only in certain cases.

SELECTIONS.

BROMIDE OF POTASSIUM IN HYPERTROPHY OF THE SPLEEN.

HYPERTROPHIES of the spleen are very frequent in Algeria in places where intermittent fevers prevail, and among the inhabitants of palustral regions in the more or less marshy plains of Chélif, of the Mitidja, Issers, etc. This organ often assumes considerable proportions, compresses the intestines, embarrasses the circulation, and determines serious accidents, sometimes death. Very often, too, this engorgement resists every form of medication known up to the present day, the most energetic, the most rational, even removal from the mephitic centre, change of country, etc.

The following is a treatment which has always given me the best results. Up to the present time, of thirty-eight observations I have not had a case of failure, so that the treatment is as efficient as simple.

The volume of the spleen does not augment only after the access of fever. There are hypertrophies of this organ in malarial localities which have never been preceded by the least febrile movement. In these cases the sulphate of quinia produces no effect whatever: it may even be injurious. On the other hand, it produces very excellent results when the augmentation of the spleen is not only recent but is also the consequence of intermittent fever. We may see these hypertrophies disappear without even being obliged to administer large doses of quinia; and if they do not thus disappear entirely, they end by yielding spontaneously to the efforts of nature and a pure air. But we are not always happy in being able definitely to cut down an intermittent fever at its start. The patient does not always take the necessary precautions to arrive at a certain and solid cure. Recurrences supervene, each one of which increases the splenic engorgement. In these cases we can rely no longer on febrifuges. We must have recourse to a medication *dégorgeante, résolutive*, which up to the present time has not given results as evident and positive as the means of which I am about to speak.

It occurs also that we may completely cut down an intermittent fever, and the engorgement of the spleen may not present the least diminution. These cases, rebellious to the sulphate of quinia, yield perfectly to this new medication.

Splenic intumescence may have different forms; sometimes it is enormous, hard, painful to pressure, even to touch, gives a sense of resistance, presents an

extraordinary diameter, reaches beyond the linea alba, crowds back and seriously compresses the intestines, pushes up the heart and left lung, simulating affections of these organs, with great interference with their functions, takes up the whole of the left hypochondrium and sometimes a great part of the pelvis, as I have remarked in an Italian working at the fabrication of vegetable hair in an insalubrious lodging on the banks of the Harrach.

The great obstinacy I have often experienced in causing these hypertrophies to disappear has always interested me exceedingly; their persistence in spite of the most rational treatment and that best observed has often discouraged patients.

A most felicitous circumstance furnished me the indications which constitute the object of this work.

M. A—, colonist and landed proprietor in the Mitidja, a very intelligent man and a close observer, had inhabited the plain for fifteen to twenty years, during which time he had often been attacked with intermittent fever which had exhausted his constitution. During the time I dwelt in this country, he had several relapses with cerebral accidents, very painful and very disturbing, with delirium, nervous agitations, etc. I had frequent occasion to examine him thoroughly during and between the attacks. The spleen was enormous, hard, greatly hypertrophied. I advised different kinds of treatment, which had often been tried before, but without any result whatever.

In the course of the last year he was seized with an accession of very violent nervous attacks. I then prescribed the bromide of potassium, three grammes (forty-five grains) daily, in one potion. I was very much surprised on the tenth day of this treatment to observe that the spleen was diminished one-half. The bromide of potassium was continued twenty-five days up to complete resolution of the spleen.

I hastened to repeat this experiment to verify the fact,—I had a great number of cases under observation, —and I always obtained the same happy results.

En résumé, we may secure complete resolution of intumescence of the spleen in different conditions, by the bromide of potassium in the dose of one gramme daily for fifteen or twenty days in an infusion of linden-blossoms, orange-leaves, etc. It is rarely necessary to prolong treatment beyond thirty days.

Here is a last observation, made quite recently :

An Arab of Turkish origin, in a very comfortable pecuniary condition, had an enormous belly, resistant, very painful in the left hypochondrium, the most pronounced anæmia, and all these conditions for six years. After a month of treatment by the bromide of potassium, he resumed his occupation. Six months have now passed, and the left hypochondrium has presented its normal aspect and state. There was no recurrence whatever. No one of the numerous varieties of treatment previously employed had given this result, although they had secured him temporary relief.

I close by remarking that by this medication in the same doses, hypertrophies of the liver yield just as readily, or at least are very much improved. I propose to speak of this subject in another paper.—*M. Dr. Ch. Bernard, médecin de colonisation at Bordj-Menaïel, in Bulletin Gén. de Thérap.—The Clinic, September 15, 1874.*

GLEANINGS FROM OUR EXCHANGES.

DIAGNOSTIC POINTS BETWEEN CANCEROUS AND SYPHILITIC ULCERS (*The Medical Press and Circular, September 30, 1874*).—1. With the cancrroid, save by coincidence, there is absence of anterior syphilitic affec-

tions. 2. With the cancrroid, evolution is much slower in kind, and the ulceration is preceded by a rather long period, during which the lesion shows itself in the state of a dry tumor, hard, and not ulcerated. There is nothing like this in tertiary syphilides, which either ulcerate at once, originally (ulcerating form), or develop infiltrations (gummy form) which ulcerate in a relatively very rapid way. 3. In the condition of ulcer the cancer still has a hard, dry, elastic base, which shows that the ulcer is formed on a morbid tissue. Tertiary syphilitic affections at the most are ulcers, with a hard, engorged base; but this does not give the sensation of a tumor beneath the ulcerations, and has not in any case the hardness of the cancer. 4. The ulceration of the cancer is redder and more fungous than that of tertiary ulcers; it bleeds more easily; secretes an ichorous sanies more diffuent, more fetid. It is often surrounded and bordered by mammillary vegetations, like raspberries or cauliflowers, etc. 5. At a certain time the cancer has an influence on the glands, which become hard, voluminous, and may even ulcerate, bud forth, and vegetate. With syphilitic affections there is no affection of the glands, at least in the enormous majority of cases, and with the exception of inflammatory and strumous complications. 6. Whilst the specific treatment remains without any action on the cancer, it is rapidly active in tertiary symptoms. It is, then, here, as in so many other cases, to specific treatment that we should have recourse when the least doubt subsists as to the nature of the lesion.

TETANUS CAUSED BY THE SPONTANEOUS OPENING OF A PSOAS ABSCESS (*Irish Hospital Gazette, October 1, 1874*).—Mr. T. Agmon Vesey reports the case of a boy, æt. 17, who had suffered for some months from a large psoas abscess which had finally burst and discharged. On the following day he felt his throat sore, and experienced some stiffness of the neck, which gradually increased and caused difficulty in mastication. The next day his right leg became very stiff, with occasional darting pains, which afterwards ascended to the abdomen and became fixed at the lower end of the sternum. He then had his first tetanic spasm, after which his condition was as follows: Face pale, brows contracted, forehead corrugated, eyes fixed, prominent, and peering, nostrils dilated, risus sardonius fearfully marked, skin covered with perspiration, pulse feeble and rapid. The sternal pain became much aggravated before each tetanic seizure. He lingered for seven days, and then died asphyxiated. Atropia was given hypodermically, in doses increasing gradually from one-sixtieth to one-twenty-fifth of a grain every fourth hour. No unpleasant consequences were produced, but as the system came under the control of the remedy there was a remission of the tetanic state, an increase in the force of the heart's beat and in the amount of urine passed, together with a cessation of the profuse perspiration, which had before been constant. The system, however, at last refused to respond to the drug, and it was discontinued.

CEREBRAL ABSCESS (*Irish Hospital Gazette, October 1, 1874*).—Dr. J. W. Moore reports the case of a girl, æt. 24, who, when she came under observation, had been ill but two days. She was much prostrated, her pulse was weak and slow (80), her temperature high (101°·7), her tongue heavily furred, and her lips partially covered with an eruption of herpes, the vesicles being filled with an opaque, pus-like fluid. There was tenderness on pressure over the occipital region. These symptoms led to the diagnosis of epidemic cerebrospinal meningitis, and the rapid supervention of hyperæsthesia of the back of the neck, with marked retraction of the head, seemed to justify that view of the case. Dilatation of the pupils occurred, greater in the right than in the left eye,—together with convergent stra-

bismus and conjunctivitis of the right eye. The patient died, comatose, within a week, and the post-mortem examination revealed a large abscess engaging most of the posterior part of the right hemisphere, and running down to the margin of the posterior lobe. The cavity of the right ventricle was distended with a whey-like, sero-purulent fluid. The third and the left ventricle also contained a quantity of the same fluid. The upper part of the spinal cord, the medulla oblongata, pons Varolii, and cerebellum were all quite healthy.

AMAUROSIS FOLLOWING FRACTURE OF THE NASAL BONES (*The Medical Press and Circular*, Sept. 23, 1874).—Dr. John W. Martin reports the case of a laborer, æt. 60, who received a blow from a stone, which inflicted a severe lacerated wound, involving the upper eyelid on the right side, and fractured the nasal portion of the superior maxilla, together with the palate, and, most probably, the lachrymal bones. It was followed by severe pain in the right orbit and temple, complete loss of sight on that side, and lachrymation, the tears escaping over the cheek. There were no symptoms of external inflammation. The inner canthus of the eye was displaced downwards and outwards. Examination with the ophthalmoscope revealed well-marked congestion of the retina as compared with that of the unaffected eye. Motions of both eyes normal. Bowels acting. General health good.

R Sol. hyd. bichloridi, ʒi
(Strength, gr. i to ʒi);
Tinct. aurantii ad ʒij.—M.

One teaspoonful to be taken three times a day, in a little water, after meals.

Strong tincture of iodine was applied to the temple.

The subsequent history was one of steady improvement and recovery of sight.

PERFORATION OF THE RECTUM (*British Medical Journal*, Sept. 26, 1874).—Dr. C. S. Jeffrieson reports the case of a girl, æt. 15, who accidentally jumped with some force upon a walking-stick, the end of which penetrated her anus, but was easily withdrawn. Symptoms of acute peritonitis occurred on the following day, and digital examination revealed a rent in the anterior wall of the rectum, which was large enough to admit the finger into the peritoneal cavity at the apex of the recto-vaginal pouch. The case terminated fatally at the end of the second day.

ARTERIO-VEINUS ANEURISM (*The Lancet*, October 10, 1874).—Mr. Timothy Holmes thinks that the study of the recorded cases of arterio-venous aneurism should lead us to derive from them the following inferences:

First. That the treatment must be directed to obliterate the orifice of communication between the artery and the vein. It is from this communication that all the secondary consequences of the affection seem to proceed; viz., varicosity of the veins, degeneration of the artery, œdema, pain, and loss of the functions of the limb. This communication may be obliterated in three ways:—1. By laying the sac open, and tying the artery above and below the wound. When this has been done, the surgeon may use his own judgment as to tying the vein also. 2. By tying the artery above and below outside the sac. 3. By compression applied to the venous orifice and to the artery above the tumor. This is best done simultaneously after Vanzetti's method. But cases have been successfully treated by first compressing the venous orifice until the latter has been obstructed by coagula; the arterio-venous is thus converted into a simple arterial aneurism, which is afterwards treated in the usual manner.

Secondly. All cases which have been dissected at a late stage of the disease prove that the artery becomes so attenuated and enlarged above the tumor that no

operative interference can then be successful. Hence the necessity for treating the disease decisively at first, and for abandoning operative interference if the case is not seen sufficiently early.

MISCELLANY.

ACCORDING to Képesy, the surgeon to the Austrian Polar expedition, chocolate, as a beverage, proved most valuable of all,—the preserved meat and vegetables in tins being also of the greatest service in sustaining the strength and spirits. Mental anxiety, however, caused by the hourly-apprehended crushing of the *Tegethoff* by the ice-fields in which it was imbedded, so far neutralized the virtues of the victualling that scurvy and affections of the lungs set in, and yielded only to the incessant bear-hunting in which the officers and crew wisely indulged to keep the faculties, moral as well as physical, occupied. The fresh bear's meat, as a change from the preserved, had also its advantages; but several of the crew succumbed,—one of them being the engineer, who died of consumption, and was buried between two basalt columns in the newly-discovered land.

Two of the foremost surgeons of Milan have recently been fined for not giving information concerning a duel which was attended with serious results. The plea of professional secrecy was brought forward, but the court refused to receive it.

THE number of medical students entered in London since October, 1873, is said to have been a little under one thousand. St. Bartholomew's heads the list with 109, and is followed by Guy's with 85.

AN extract for tanning leather is now prepared from *Polygonum amphibium*, which grows extensively in the West. The plant can be had in large quantities at two dollars per ton, and contains about twenty-two per cent. of tannic acid.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM NOVEMBER 3 TO NOVEMBER 9, 1874, INCLUSIVE.

CUYLER, JOHN, SURGEON.—Detailed as member of Army Retiring Board, to assemble in New York City on the 16th instant. S. O. 240, A. G. O., November 5, 1874.

HEAD, J. F., SURGEON.—So much of S. O. 229, c. s., A. G. O., as relieves Surgeon Head from duty in Department of Dakota, is revoked. S. O. 237, A. G. O., October 31, 1874.

MOORE, JOHN, SURGEON.—Detailed as member of Army Retiring Board, New York City. S. O. 240, c. s., A. G. O.

KNICKERBOCKER, B., ASSISTANT-SURGEON.—Assigned to duty as Post-Surgeon at Fort Colville, W. T. S. O. 149, c. s., Department of the Columbia.

NOTSON, W. M., ASSISTANT-SURGEON.—Assigned to duty as Post-Surgeon at Fort Cameron, Utah Territory. S. O. 162, Department of the Platte, October 30, 1874.

BARTHOLOF, J. H., ASSISTANT-SURGEON.—Assigned to duty as Post-Surgeon at Camp Harney, Oregon. S. O. 149, Department of the Columbia, October 22, 1874.

DE HANNE, J. V., ASSISTANT-SURGEON.—Assigned to duty as Post-Surgeon at Fort Mackinac, Michigan. S. O. 220, Military Division of the Atlantic, November 6, 1874.

SATURDAY, NOVEMBER 21, 1874.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON THE USE OF DIGITALIS IN DISEASES OF THE HEART.

No. II.

Delivered at the Philadelphia Hospital

By H. C. WOOD, JR., M.D.

Reported by Dr. JOHN GUITÉRAS.

AFTER a brief résumé of the previous lecture, Dr. Wood passed on to explain how digitalis does good in the individual valvular lesions. After briefly explaining the distribution of the cardiac cavities and the mechanism of the valves, he took up the consideration of the mitral.

There are only two possible conditions that can affect this valve: one is constriction, and the other insufficiency.

Suppose we consider, first, cases of mitral deficiency. As previously stated, when we administer digitalis we give the ventricle more time to fill up with blood and more force to propel it. But you will tell me that this excess of force is applied to one opening as much as to the other, to the leak as well as to the open mouth of the aorta. This is true; but you must remember that the leak is usually a comparatively small and irregular orifice, so that when the force of propulsion is increased, the resistance of friction increases much faster at the leak—*i.e.*, the small, irregular, partially obstructed opening—than at the large, smooth, aortic mouth; consequently, the greater the force of propulsion, the less blood proportionately is lost through the damaged valve, and the more blood proportionately is forced into the aorta.

In mitral stenosis or constriction, during diastole the ventricle only fills partially with blood; because the opening through which the blood comes is narrowed, and because the time allotted for the purpose is shortened rather than increased, owing to the irritated state and rapid action of the viscus. Now, digitalis lengthens this period of diastole, and if the orifice is narrowed by one-half the drug may give the ventricle double the time, so that it may fill up and be able to contract with increased force upon a good volume of blood. Instead of a hundred abortive contractions of an empty ventricle, there will be a less number, seventy, or sixty, or even fifty strong contractions of a ventricle full of blood; of course the gain is enormous.

It is unnecessary to follow out the same reasoning for the right auriculo-ventricular valves, because the physical conditions are identical, and because primary disease of the right side is a great rarity.

We will pass, then, to speak about the two conditions that may affect the aortic opening,—*viz.*, constriction and insufficiency. In aortic constriction we have no leakage, but a constant impediment to the flow of blood from the heart; an impediment

which impresses the ventricle chiefly during systole, stimulating it at such times enormously, and probably for this reason almost constantly giving rise to hypertrophy rather than dilatation. Because the hypertrophy is, in these cases, so often fully compensatory, or even excessive, digitalis is generally not indicated, and often has done harm; from this has arisen the notion that digitalis is a dangerous drug in aortic disease of the heart. This is a mistake; it really makes no difference which valve is diseased. The question simply is whether the hypertrophy is excessive, sufficient, or insufficient. There are cases of aortic obstruction in which the hypertrophy is deficient, and in these digitalis is indicated. In aortic regurgitation the leakage does not occur during the period of cardiac activity, but when the heart is at rest, and the blood is thrown back against the semilunar valves by the arterial contraction. Digitalis, by lengthening the diastole, may thus increase the trouble; but yet, even in these cases, when the left ventricle has been so overpowered that it cannot unload itself of the blood that pours in from the two openings, digitalis may give the muscle strength to overcome temporarily the trouble. It is evident, however, that in aortic regurgitation the drug must be used with especial caution.

In the use of digitalis, so far considered, the drug has been given with the idea of affording temporary relief. To show how temporary this relief may be, let me tell you that the case which I showed you at my last lecture is much worse, and that the drug no longer affords the man any relief. To show you how great this relief may be for an instant, even when the patient is *in articulo mortis*, let me read to you some notes furnished by my able resident, Dr. Berens, in regard to a case of mitral and tricuspid disease which recently died in this hospital. The fatal paroxysm, it should be stated, came on rather suddenly. Dr. Berens says,—

On my arrival in the wards, the patient was found sitting up, supported in a chair, completely unconscious, with cyanosed face, labored respiration, pulse weak, intermittent, irregular, and rapid to the last degree. He received immediately ten grains of carbonate of ammonium hypodermically, as he was unable to swallow. In a few moments he revived sufficiently to take some whisky. Pulse now was about 160, with its character unchanged. A hypodermic injection of digitalin, gr. $\frac{1}{5}$, was now given. No change being noticeable in twenty minutes, the dose was repeated. Fifteen minutes after this, the pulse began to alter, and in less than five minutes had fallen to 90, and was comparatively quite regular and strong; the respiration changed also, and the man recovered consciousness. After a short time, upon expressing the desire to lie down, he was permitted to return to bed, and soon after lapsed into what seemed a quiet sleep. About an hour after this, the pleural effusion seemed to overcome him; he started up panting and coughing, then fell back, and in less than half an hour expired, evidently killed by the lung-complication, as his heart retained its regularity to a great extent up to the last moment. At the post-mortem an extraordinary amount of valvular degeneration was revealed, there being extreme mitral and tricuspid stenosis and insufficiency. The lungs were œdematous, and the cavity of the thorax filled with serous effusion.

In the earlier stages of cardiac disease, digitalis helps in effecting what may be called a cure. It is a mistake to suppose that the existence of valvular disease necessarily dooms a patient to a short life, or to one of suffering, or even of decided invalidism. If the disease commences before the age of nineteen, it is very apt to terminate fatally before thirty; but if it develops after puberty, the victim may enjoy a comfortable life of many years' duration. I have long had under my care an old lady who was as a child dandled on the knees of General Washington, and who for years was a patient of Dr. Physick, but who yet, at eighty-five, enjoys comparatively good health, although from time immemorial she has suffered with very decided mitral insufficiency.

Nature cures valvular lesion, or rather protects itself against the ill effects of valvular lesion, by compensatory hypertrophy; and the rational aim of treatment is to aid nature in this, and, above all, to prevent that failure of cardiac strength that ends in cardiac dilatation. Digitalis will not only aid in averting dilatation, but will also aid very greatly in the production of hypertrophy.

Dilatation is, no doubt, partly owing to a gradual stretching of the heart-walls during diastole from over-repletion of the cavities; digitalis enables the heart to empty itself, so that there is much less cause for dilatation, and also, by toning the muscular fibres, gives them strength to resist the tendency. To explain the action of the drug in producing hypertrophy, we must refer to the cardiac circulation. The coronary arteries are given off at right angles from the aorta, so that there is little tendency for the blood, just squirting out from the heart as a solid stream not yet broken by contact with the arch of the aorta, to leave the wide-open track and pass into the small coronary arteries; besides, the mouths of these small vessels lie so close to the edges of the semilunar valve that these either close them entirely or else deflect the blood-current from them. More than this, during the systole, every vessel in the heart-wall is forcibly closed, precisely as the sinuses of the uterus are closed when you induce uterine contraction in post-partum hemorrhage. But when the recoil comes, the elasticity of the aorta drives back the blood towards the ventricles, shutting down the semilunar valves, and of necessity forcing the blood into the cardiac vessels. These are now relaxed, so that the vital current enters into every portion of the viscus. During the diastole, then, the arterial blood enters the heart; during the systole the venous blood is squeezed out of it, the muscle becoming so dry and so bloodless that in the lower animals it is often absolutely white.

It is readily seen that when, owing to valvular disease of the heart, the general circulation is failing, the cardiac circulation must suffer most seriously. Although a great number of imperfect cardiac contractions occur, yet a small amount of blood is thrown into the arterial system, making the reflex from the empty aorta a very feeble one. More than this, the action of the heart is so rapid, the diastole so short, that time is not allowed for

the arterial blood to enter and nourish the cardiac tissue; and, the systole being also so feeble and incomplete, the venous blood is not thoroughly expelled from the heart-walls; so that there is a diminution of the arterial supply, and an imperfect draining of the venous blood. The cardiac circulation is therefore doubly impaired, and imperfect blood-supply to an overworked organ means defective nutrition and rapid degeneration. Digitalis, by prolonging the diastole, gives time for the cardiac vessels to fill up; by increasing the power of the systole it empties the cardiac veins, and at the same time, by causing more blood to be thrown into the aorta, gives the arterial system more of the vital fluid to contract upon and to propel into the coronary arteries. The effect of the change wrought in the cardiac circulation by digitalis is probably tenfold that achieved in the general system; and therefore, by furnishing nutriment, the drug exerts a most powerful influence in favoring the production of hypertrophy. When the cardiac muscle has already undergone change, digitalis can effect but little: hence the importance of administering the drug with iron and other tonics in the early stages of heart-disease.

But little time can be devoted to-day to the question of the administration of digitalis. Probably the infusion is the best form. If there is much dropsy, the drug may be given in pill form, combined with squill, one grain of each, three times a day. Of the tincture you can give five, ten, fifteen, or twenty drops every four, three, or two hours. In all cases you increase the dose gradually until some effect is attained, but you must do this very carefully, as digitalis is eliminated very slowly from the system; and sometimes, when it has been taken for a long time, a sudden poisonous effect results. Its effects, indeed, are always slow to show themselves, and they also subside very slowly, so that the medicine should be at once withdrawn temporarily when a decided influence is apparent.

Some time ago there was a woman with hydrothorax in our wards who was taking ten or fifteen drops of the tincture three times a day. This was continued for many weeks without any decided effect. One Sunday the pulse was found to have fallen ten beats,—it was then 80. On Monday, the pulse being 70, the digitalis was discontinued. On Tuesday the pulse was 60; on Wednesday it was 50, and on Thursday it was 40. With rest and opium the patient recovered, but for a week afterwards her pulse never went above 50.

I do not want to impress you with the idea that digitalis is a dangerous drug. It has been given in doses of a half to one ounce, without any dangerous symptoms. The tincture, as you know, has been given in large doses—even an ounce—in the treatment of acute alcoholism, and the old school of therapeutists have been at their wits' end to know why it did not kill patients already suffering with the great nervous exhaustion of delirium tremens. They even suggested that the alcohol in the tincture counteracted the depressing action of the drug; but what are a few drops of alcohol to a man who is in the habit of taking over a pint a day? And how could

such small doses of the stimulant counteract the enormous dose of such a powerful sedative as digitalis has been supposed to be? Digitalis in these cases did not kill the patient, gentlemen, because it is not a cardiac sedative, but is a cardiac stimulant.

Do not, therefore, be afraid of digitalis in valvular heart-disease. Use it cautiously but boldly, use it freely but judiciously, and you will find that it deserves even a better title than that "of an opiate for the heart."

ORIGINAL COMMUNICATIONS.

FRACTURE OF THE FRONTAL AND TEMPORAL BONES SUCCESSFULLY TREATED.

BY JOHN FOOTE, M.D.,

Archibald, Pa.

Reported by J. V. SHOEMAKER, M.D.

WEDNESDAY, June 24, 1874, about 7 A.M., while James F., eleven years of age, was playing on the railroad-track, he was struck on the forehead by that part of the locomotive called "the pilot." The doctor was called a few minutes after the accident, and found a wound five inches in length, and about one inch above the superciliary arches of both orbits. The fracture was traced across the os frontis from one temporal bone to the other. The temporal bones themselves were also fractured their entire length. The skull was lifted up half an inch at the external wound. The bleeding was profuse, and portions of the brain were protruding through the entire length of the wound. The pulse was 88, and irregular; the pupils were natural, but consciousness was partially lost. The wound was washed by pouring water on it, which brought away about half an ounce of the brain-material. The external wound was then drawn together in its middle by a suture. Inserting the needle brought a sharp cry of pain from the patient. A sponge saturated with a weak solution of carbolic acid was then nicely packed in the open portion of the wound, and a bandage was applied so as to press the sponge lightly into the wound.

The patient asked for a drink of water, and tried to pull off the bandage. Pulse 88, irregular and full. On removing the bandage, the substance of the brain oozed out. The sponge, on examination, was found to be saturated with blood and brain-substance. Five grains of bromide of potassium and ten drops of tincture of digitalis were given every four hours. Vomiting set in, and about the same time the right eyelid became very much tumefied.

Thursday, 25th, 7 A.M.—Pulse 75, full, and irregular. The middle meningeal artery of the dura mater could be seen beating strongly on the right side. The patient rested well during the night; the vomiting had not recurred. On taking off the bandage, more brain-matter was lost, and the sponge was saturated with blood. During the night and day his breathing was difficult. The face became very much swollen, and the right eye was completely closed. Warm milk and toast-water were ordered for him, and the bromide of potassium and digitalis were continued.

Friday, 26th, 7 A.M.—Pulse 76, and regular; patient had a good night's rest. The pupils were natural; consciousness returned for the first time; he was able to recognize those around him, but could not tell how he had been injured. Tongue slightly coated. Dr. R.

Squires, of Scranton, met the doctor in consultation, and advised the continuation of the treatment.

Saturday, 27th, 8 A.M.—Pulse 76, and regular; passed a comfortable and quiet night; on awakening, complained of feeling hungry. He took the substance prepared, and a cup of tea. Absence of pain. The right eye remained closed, and the brain-substance continued to come away in small pieces, but the oozing of blood had ceased; tumefaction had extended to the left side of the face. The bowels were freely moved by citrate of magnesium. The sponge was removed from the wound, which was dressed with lint saturated with a weak solution of carbolic acid.

Sunday, 28th, 8 A.M.—Pulse 80; patient sitting up, taking milk and toast freely. The brain-substance ceased to come away, and that in the wound was of an ashy-gray and light-brown appearance.

Monday, 29th.—Suppuration set in; the wound looked yellow, and granulations were beginning at the left corner. On removing the sutures, adhesive strips were applied over the middle of the wound, and it was again dressed with lint saturated with a solution of carbolic acid. As he became very restless and feverish, full doses of bromide of potassium and digitalis were given. The quieting effect of the bromide could be seen on the branch of the middle meningeal artery of the dura mater half an hour after administering it. Four hours passed before the digitalis began to act and reduced the frequency of the pulse. By means of the bromide and digitalis the pulse was kept below 90. The doses had to be regulated according to the determination of the blood to the brain. The citrate of magnesium was given, and soon caused a free action of the bowels.

Wednesday, July 1.—Pulse 88, full and irregular; tongue clean; bowels torpid; refused to take nourishment. The pupils were dilated; was not able to see with the right eye, and complained of cramps in the right leg. The wound suppurated freely, and was granulating rapidly.

Thursday, July 2.—Much better and brighter. Paralysis of the left side of the face well marked; also loss of vision in the right eye. Wound granulating.

Friday, July 3.—Pulse 80, and full; loose piece of the frontal bone was removed; on the right side there is a large piece of the brain protruding half an inch above the skin, covered with healthy pus.

Thursday, July 9.—The wound has continued to heal. Loose pieces of bone, from one-quarter to one-half and even three-quarters of an inch long, and of different breadths and thicknesses, have been frequently removed. He has regained the sight of the right eye, and the paralysis of the face is gradually disappearing.

Seven weeks from the time of the injury the wound was entirely healed, and he went to work in the coal-mines, perfectly recovered in body and mind.

A CASE OF EARLY MATERNITY (*The Medical Record*, October 15, 1874).—Dr. E. A. Goodridge reports the case of a colored girl who began menstruating shortly after her eleventh birthday, and continued to do so regularly until the month previous to her twelfth birthday, when conception took place. Gestation was completed without the occurrence of any special functional derangement. The head presented in the left occipito-iliac position; labor lasted seven and a half hours. The infant was a female, weighing seven pounds. There was a copious lacteal secretion on the third day, after which the mother continued to supply sufficient nourishment for the sustenance of her child. The mother's age at the time of delivery was twelve years, eight months, and twenty-five days.

NOTES OF HOSPITAL PRACTICE.

JEFFERSON MEDICAL COLLEGE.

CLINIC OF PROF. S. D. GROSS.

FEMORAL ANEURISM.—LIGATION OF EXTERNAL ILIAC.

JAMES L., æt. 34; occupation, that of a warper in a cloth-manufactory.

Gentlemen,—The case which now presents itself for consideration is one of much interest, both from its gravity and comparatively infrequent occurrence at this period of life. This affection is more common in advanced age, and in persons whose employment subjects the lower extremities to severe muscular exertion, producing sudden strain upon the vessels.

This man, in the prime of life, has always enjoyed very good health, and his occupation is one not requiring a great amount of muscular strain or activity. About two months ago, he observed a tumor situated in the groin at its anterior aspect, two inches below Poupart's ligament. He had never received an injury in this locality. The swelling gave him no pain, and produced so slight inconvenience that little attention was paid it, till within the last month it has increased so much that he has now applied for relief. Latterly, he has been losing flesh. The heart's action is weak, and the pulse 68. You observe, in the position before indicated, a tumor, pulsating synchronously with the heart's contraction. Auscultating the tumor, I hear an aneurismal blowing sound. Placing my fingers just below Poupart's ligament, in the line of the femoral artery, and making firm compression, the pulsatory movement and blowing sound are completely arrested; and, on pressure, the tumor almost completely disappears. On the other hand, making compression below the swelling, the tumor is notably enlarged.

There is no difficulty in diagnosing this tumor, it being manifestly an aneurism of the femoral artery. Had we seen the case at an earlier period, the inquiry would arise if it were not a psoas abscess pointing in this locality, a bursa, or an enlarged lymphatic gland, which, probably receiving an impulse from the artery, caused the swelling to simulate aneurism. But the history of the case, the fact that the tumor pulsated from the moment of its development, and a careful examination, promptly set aside the possible existence of any such affections.

You are aware that an aneurism is a tumor occupied by blood, and communicating with an artery either partly or entirely deprived of its integrity.

Aneurisms are distinguished, in reference to the causes producing them, into two kinds,—viz., traumatic and spontaneous aneurism. They are also designated as true and false; the former term being applied to that species of aneurism in which one or more of the arterial walls form a part of the tumor; the latter, on the contrary, one in which all the tunics of the vessel have given way, and the aneurismal sac is formed by the condensed cellular tissue.

Spontaneous aneurism is of more frequent occurrence than the traumatic; it is more common in some arteries than in others, and more males than females are attacked by it. The artery which suffers most frequently is the aorta, throughout its whole extent; and the next in point of liability are the popliteal artery, the femoral, common carotid, subclavian, innominate, axillary, and external iliac. Spontaneous aneurism results from the earthy or atheromatous degeneration of the arteries rendering their walls preternaturally brittle, causing them to yield more readily to the impulse of the blood or severe muscular action.

The case before us is doubtless a true aneurism of the

sacciform variety, the middle and internal coats having been ruptured, and the sac formed by the dilated external tunic. The aneurismal thrill is produced by the passage of blood from and to the artery, through the orifice communicating between the sac and vessel; and the thrill, which is here not very marked, is due to the comparatively large size of the aperture.

The effect and termination of aneurism pursuing its course without the intervention of art are interesting and remarkable. The effects produced upon the surrounding parts are essentially mechanical in character, varying with the size and situation of the tumor. The functional disturbance is also in proportion to the amount and importance of the structure involved. It is not less remarkable than gratifying that, although the prognosis of aneurism is so extremely unfavorable, nevertheless a spontaneous cure is occasionally effected; thus, cases bidding defiance alike to medical and surgical skill eventuate in complete recovery. This, however, is unfortunately the exception, and not the law, the aneurism increasing progressively until it finally bursts, and terminates the life of the individual.

The treatment of external aneurisms, or those properly belonging to the domain of surgery, dates back to the time of Celsus. But the lapse of time from that period to the present day has marked great and necessary modifications in the treatment of this class of maladies. The method of treatment at that time consisted in laying open the tumor, turning out its contents, and applying the hot iron to the extremities of the severed artery, to seal up its mouth. From this treatment almost every patient perished from secondary hemorrhage.

Subsequent to this, we find other operations not much more fortunate in their results, until Mr. John Hunter first introduced the operation of ligating the artery at the cardiac side of the tumor, the results of which were much more gratifying than any of the previously employed measures. This operation was effected by casting a ligature about the vessel sufficiently tight to completely occlude its calibre, and at a distance on the cardiac side of the tumor to reach beyond the portions involved in the degeneration. After this, a teacher in the old School of Surgery, at Paris, suggested ligation on the distal side of the tumor in cases in which, on account of the position of the aneurism, Hunter's operation was impracticable.

Among other methods which have been employed and are deserving of consideration, are forced flexion and compression. The former mode of treatment has been attended with very good results, and in one case in which I employed it it was completely successful. The latter method was not very successful as first employed, but, having undergone some modifications by Dublin surgeons, compression by mechanical appliances now ranks among our resources of treatment. Digital compression, first proposed by a surgeon at Padua, is a mode of treatment which has not received as much attention as it deserves. Statistics bear very favorable records from the employment of digital compression, and some time ago complete solidification of the contents of the sac of a large aneurism of the upper third of the femoral artery, was effected in forty-six hours by digital compression alone. In this case I propose to adopt either ligation by Hunter's method, or forced flexion. This consideration will be reserved until the next clinic, when the decision will be acted upon.

Gentlemen,—Since this patient was last before us, to arrive at the best mode of procedure for his relief forced flexion was temporarily resorted to, but it was productive of so much pain that ligation was considered to be the better method, and to-day I purpose performing the operation before you. The high situa-

tion of the aneurism will render it necessary to ligate the external iliac artery, in order to accomplish the desired end.

This operation consists in making a curvilinear incision, with the convexity downward and outward, commencing from an inch to an inch and a half above Poupart's ligament, just outside the external abdominal ring, carrying it upwards on a level with the anterior superior spinous process of the ilium, and about two inches to its inner side. The first cut extends through skin and superficial fascia; and if any small superficial arteries are severed, they are secured before any further procedure.

By this incision the aponeurosis of the external oblique muscle is laid bare, and is divided upon the grooved director. Beneath this in order come the internal oblique and transverse muscles, which are divided, and finally the transverse fascia is exposed, being recognizable by its whitish opaque appearance. A small hole is cautiously made in this membrane, which is slit open to the extent of the other incisions. The next procedure, and one of the most delicate, is to separate the peritoneum from its attachment in the iliac fossa. This having been accomplished, the iliac artery will be found pulsating at the bottom of the wound, with the iliac vein behind it above, and on the inside below; while on its outer side, and on a somewhat lower plane, lies the anterior femoral nerve. Care must be taken not to include either of those structures in the ligature. The sheath of the artery being cautiously penetrated, the aneurism-needle, armed with a ligature, is gradually passed around the vessel from within outwards, and firmly tied. The wound is now to be brought together, and this should be done by introducing the needle down close to the peritoneum, or, what is better, by bringing the different structures together and tacking them separately; this precaution being taken to insure union between the parts, and thus obviate the liability to hernia when the patient begins to walk about. The after-treatment requires the patient to be put carefully in bed and placed in such a position as to relax the parts, and the limb from which the supply of blood has been cut off to be kept warm.

An anodyne should be given, and the bowels locked up for the space of several days, and when moved only the mildest measures must be adopted. The patient is now under the influence of an anæsthetic, and I shall operate in the manner just described. The bowels were emptied of their contents just previous to coming into the room, which adds to the facility and safety of the operation. I have divided successively the superimposed structures, and detached the peritoneum from its connections, and the artery is plainly felt at the bottom of the wound. A silk ligature, well waxed, is now passed around the vessel and tied with sufficient firmness; and you observe that the tumor immediately ceases its pulsations. The integumental and muscular structures are accurately approximated by sutures. An anodyne will be given, the bowels locked up, the temperature of the apartment regulated, and light diet with cooling drinks ordered; the supply of blood being cut off by the external iliac, the collateral circulation will be established mainly through the anastomosing branches of the gluteal, sciatic, obturator, and pudic arteries, with the circumflex and deep femoral branches.

It is four days since ligation of the external iliac was performed, and the patient is doing well in all respects. There has been but slight change in temperature, no shock to the system, he has slept well, appetite is good, and the pulse from seventy-three to seventy-four. The bowels are still locked up, and will be kept so for some time yet. The dressing has been changed, simply applying lint, saturated with olive-oil. There is no suppu-

ration, and the wound has united by adhesive inflammation. The ligature will probably come away in ten to twelve days, dependent upon circumstances. He has been taking gr. ii quiniæ, gtt. xx tincturæ ferri chloridi, four times daily, and gr. iv opii once a day, with tincturæ aconiti radidis, gtt. iv four times a day.

Three weeks have elapsed since the operation, and the patient continues to progress favorably. The bowels were not moved for fourteen days, from which, however, he did not suffer in the least. He has now one movement daily. The wound is all healed, except the part embraced by the ligature, which is still retained, no traction having been made upon it.

It has been five weeks since the operation. The ligature came away this morning. In the past fortnight there was some swelling and elevation of temperature in the tumor, and fears were entertained that the clot was undergoing softening. The aspirator was introduced to draw off any fluid that might be present, but little was found. After this, a small opening appeared, from which was discharged for a few days a small amount of grumous blood admixed with pus.

The danger is now past, although for a time secondary hemorrhage was feared. The ligature, detached by ulcerative absorption, came away itself, gentle traction having been made. He is now taking no medicine.

Five weeks and four days have elapsed since the operation, and to-day the patient will be sent home. The tumor has completely disappeared. The wound in the abdomen is healed, except a small spot of granulation at its most dependent portion. He must remain quiet for ten days after his removal home, when he may commence to walk about.

ST. MARY'S HOSPITAL.

SERVICE OF DR. J. EWING MEARS.

Reported by H. D. HEINITSH.

GUNSHOT WOUND OF THE FORE-ARM, INVOLVING THE ULNAR ARTERY AND NERVE.

SEPT. 15.—J. D., æt. 20, was admitted to the surgical wards of the hospital, suffering from an extensive lacerated wound of the ulnar surface of the forearm, caused by a charge of reed-bird shot. At the time of the receipt of the accident the patient was attempting to draw his gun from beneath the seat of the boat in which he was hunting, the muzzle being directed towards his body. In this effort the hammer of the gun was caught by the seat, and the weapon was discharged, the load—one ounce and a half of reed-bird shot—striking the anterior and lateral surface of the left forearm in the upper ulnar region, at that point where the ulnar artery is covered by the superficial flexor muscles. Profuse hemorrhage occurred immediately, but was checked by the application of the subsulphate of iron, made by the physician called.

On his admission to the hospital the wound was carefully examined by Dr. Eaton, the resident physician on duty in the surgical wards, who found a slight oozing from the wound. A compress and bandage were applied, and the arm was placed in an elevated position.

On making an examination the day following, the hemorrhage was found to be effectually checked; the wound was quite extensive, measuring eight inches in the long diameter and four in the short diameter. The integument was as cleanly removed as if excised by a sharp cutting-instrument; no shreds or portions were found attached; the border was sharply defined in the

entire circumference of the wound. The adjacent surface was blackened by the burnt powder, and the surface of the wound was covered with coagulated blood and the Monsel's salt. No pulsation could be detected in the ulnar artery. The fore-arm was greatly swollen, and there was a slight erythematous blush present. The entire fore-arm was enveloped in a poultice of flaxseed meal and yeast, the sound integument having been painted with solution of iodine and alcohol in equal portions. A saline purge was administered, and good diet prescribed. In two days the surface of the wound was quite completely cleaned by the action of the poultice, and the erythematous blush had disappeared. On examination, it was found that a portion of the charge had entered the tissues at a point corresponding to the upper third of the ulna, where the superficial flexor muscles pass across and down the fore-arm from their point of origin,—the internal condyle of the humerus. The cavity made by the charge was filled with wadding and a quantity of reed-bird shot. A probe was introduced, and it was found that the bone had not been injured. The distal portions of the severed ulnar artery and nerve were seen in the wound. The proximal portions could not be seen, and it was not thought advisable to make any extended search for them. It was estimated that three to four inches of the artery and nerve had been destroyed.

An examination to test the area of loss of sensation was made, and it was found to correspond to the surface supplied by the ulnar nerve. There was also complete flexion of the little finger, with partial flexion of the ring-finger.

In the course of a few days the poultice was discontinued, and the wound was dressed with carbolized oil. Under this dressing granulations sprang up, and the reparative process progressed rapidly.

Dr. Keen hastened this process, after taking charge of the wards, October 1, by skin-grafting. Out of a number of graftings two became attached, forming small islets.

October 18.—The wound has contracted in size, now measuring seven inches in length and three and one-half in breadth. The index- and middle fingers are somewhat flexed by the adhesions formed between the muscles of the flexor group. The area of loss of sensation still remains as at first described. The patient, after his discharge from the hospital, was placed under the care of Dr. S. Weir Mitchell, with a view to the accurate and careful study of the conditions following the nerve-lesion.

LACERATED WOUND OF THE LEG, PRODUCED BY WADDING FROM A SMALL CANNON.

July 4, 1874.—James M., æt. 40, was admitted to the Hospital for wound of the leg, produced in the following manner. While crossing the street, a small cannon, eighteen inches in length, one and a half inches in bore, was fired, at a distance of forty feet, in the direction of the patient; the wadding, which consisted of paper, striking the left leg of the patient midway between the knee-joint and ankle, on the outer side. The wound produced was three and a half inches long, two inches wide, and extended in depth to the inter-osseous membrane. The extensor longus digitorum muscle, with the tibialis anticus, were lacerated, together with the soft parts in immediate relation. This was the condition and extent of the wound when the patient was admitted. On examining the wound, it was found to contain a foreign substance, which, being removed by Dr. Eaton, the resident physician, proved to be the wadding with which the cannon was loaded; a small piece of the patient's pantaloons was also found, which had been forced into the wound. All foreign substances being removed and the parts cleansed, a poultice was

applied, and was renewed twice daily. Some sloughing occurred, accompanied by a fetid, sanguinolent discharge, which became diminished in quantity and less offensive on the application of carbolized oil,—one drachm to six of oil. As the sloughing occurred, the portions of tissue were removed. In a few days, granulations appeared, forming very rapidly, and the wound was soon healed.

The case is interesting because of the amount of injury done to the parts by the wadding at the distance from the patient at which the cannon was fired. The mass, when dried, weighed one hundred and eight grains.

TRANSLATIONS.

HEMORRHAGIC LARYNGITIS (Dr. A. Böcker: *Berlin. Klin. Wochenschrift*, No. 15, 1874).—In the first of the two cases of this affection which have recently been under the observation of Dr. B., the patient was a servant-girl aged 23 years, who had been affected with a cough for two weeks, and had, during the eight days prior to her admission, entirely lost her voice. At the same time she became affected with shortness of breath, and her sputa became tinged with blood. An examination of the thorax revealed nothing abnormal, but the laryngoscope showed that the mucous membrane of the entire larynx was intensely red and swollen, while the vocal cords were covered with coagula and streaks of blood, so that their mucous membrane could scarcely be distinguished. When the respirations were of moderate frequency and depth, nothing abnormal was noticed; but if the breathing was at all forced, a whistling sound was produced by the swelling of the mucous membrane. The diagnosis of acute laryngitis, with effusion of blood upon the free surface of the mucous membrane, was made. In this condition of the larynx, there could be no question of active treatment by cauterization with the nitrate of silver, as there would be too great risk of increasing the irritation and inducing still more hemorrhage; and inhalations of a solution of common salt to which laudanum had been added were ordered. During the first few days after admission the sputa were still tinged with blood, but a rapid improvement took place, and the girl was soon discharged from the hospital and treated as an out-patient. A year later, she again presented herself with symptoms of acute laryngitis, but of less intense character and unaccompanied by hemorrhage. Dr. Böcker thinks that in the treatment of such cases care should be taken not to increase the swelling by any irritative measures, and that when favorable results have followed cauterization it has been in spite and not in consequence of it.

In the second case the patient was a man aged 52, who stated that he had always enjoyed good health and had not suffered from hoarseness. Five weeks previously, he had experienced tickling and pricking sensations in the larynx, but had had no cough. After this condition, however, had continued for some time, cough and hoarseness set in, and the patient found himself compelled to seek medical aid. By a laryngoscopic examination, it was found that there was an anæmic condition of the mucous membrane of the pharynx and larynx, and that at the junction of the vocal cords with the posterior wall of the larynx there were upon both sides ulcerations, which were surrounded by reddened and swollen mucous membrane. These ulcers were cauterized three times with a solution of the nitrate of silver, but, as no improvement was seen, the solid stick was applied to the ulcer upon the left side. This operation was followed by moderate coughing, which,

however, did not last long, and upon examination the action of the caustic upon the ulcerated surface was distinctly seen. Soon afterwards, the patient, while in the street, was attacked by a spell of coughing, which was so severe that he was compelled to stand still. The cough was very unpleasant and painful, and was accompanied by a burning sensation in the larynx. On the next day the cough had vanished, but the voice was harsh and almost gone, and there was some difficulty of breathing. Four days after the cauterization, the larynx was examined, and it was found that there was a marked redness in the vicinity of the ulceration, while the rest of the laryngeal mucous membrane was pale, and at some points there were evidences of hemorrhage. In the course of a few days the swelling and hemorrhage disappeared under a continuance of the inhalations.

In both of these cases the hemorrhage was due to the severe spells of coughing which occurred. The same result is not unfrequently seen in the eye after severe vomiting, which may give rise to effusion of blood beneath the sclerotic portion of the conjunctiva.

CATARRAHAL OPHTHALMIA IN SPAIN.—Dr. F. G. Jimenez (*El Anfiteatro Anatomico Español*, Sept. 15, 1874), in an article on the "Use of Calabar Bean in Inflammations of the Cornea," says, "Inflammations of the different structures of the eye are very frequent in this part of the country, and a great number of persons are annually afflicted by catarrhal ophthalmia, but, fortunately, this is promptly subdued by the application of silver nitrate, so that we rarely see those chronic conditions and troublesome ulcerations which were before so common.

"Our treatment of keratitis is reduced to the use of calomel and opium in small doses (gr. $\frac{1}{4}$), instillations of silver nitrate (gr. iv to f $\frac{3}{4}$ i aquæ) alternating with atropia sulphate (gr. i to f $\frac{3}{4}$ i aquæ), with mercurial inunctions and derivatives to the intestinal canal."

He relates a case of keratitis complicated with iritis, in which it seems to have been the practice to use the calabar-extract to shut out the light by contracting the pupil, and also to prevent adhesions between the iris and adjacent structures. Having, besides, the indications which he quotes from Trousseau of "painful sensation, congestion of the conjunctivæ, and supraorbital neuralgia," he applied the extract, but abandoned it after a few applications, on account of the irritation which it produced, and cured his case with atropia and antiphlogistics. He continues: "I have applied the calabar according to the phenomena which Trousseau has mentioned, and what good has it done? I believe that it has been very prejudicial. The free use of atropia has been generally sufficient to prevent adhesions, as well as to tear away those formed before coming under treatment. I have never been mortified by a failure; it has always responded to my hopes. In a case of hernia of the iris surrounded by the lymph of the cornea, the result of an ulcer, the treatment consisted in the application of the calabar-extract until the pupil was contracted and the iris was liberated, and a most happy issue was obtained. In these cases, and only these, do I believe the medicament indicated, and then the formation of the hernia must have been very recent. This treatment, then, is one which is rational, and which theory may approve and practice sanction."

W. H. W.

CASE OF GENERAL ATROPHY OF THE SKELETON (reported by Dr. D. P. Gonzalez de Velasco: *Ibid.*, Sept. 15, 1874).—A woman æt. 21 years, of lymphatic temperament, in a condition of the most complete marasmus and emaciation, who appeared to have no other anatomical elements in her economy than skin and

bones, and who had suffered various exsections of the bones of the upper extremities, which were thought to be carious, presented herself one day at the Clinic of the Faculty of Medicine of Madrid, in order to have an operation upon the larynx, which was supposed to be diseased in a like manner.

She was sent to the General Hospital, where she soon after died. A very careful and minute autopsy was made, and it was found that the elbow-articulations and the lower half of the left ulna were absent, probably from not having been reproduced after excision; the atlas had been dislocated from the axis, the cruciform, transverse, and articular ligaments had been ruptured, and the two bones were ankylosed firmly together from the odontoid process around the posterior arches; the atlas being in an oblique position to the axis and compressing the medulla spinalis.

W. H. W.

INJECTION OF ALCOHOL IN HYDROCELE (*Ibid.*, Sept. 15, 1874).—Dr. Surmay reports another case of voluminous hydrocele cured by the injection of alcohol. After puncturing the tunica vaginalis and letting out more than a litre of fluid, he injected ten grammes of strong alcohol at the temperature of 36° C. into the cavity, and let it remain. In twenty cases treated by this method he obtained eighteen cures, with only one injection for each. The remaining two cases were cured by the second operation.

THERAPEUTIC NOTES.

LOCAL APPLICATION IN VEGETATIONS.—M. Duchaussoy uses a powder similar to the following in the affection sometimes known as "venereal warts:"

℞ Pulv. sabinæ,
Pulv. aluminis, āā ʒss;
Pulv. hydrarg. chlor. corros., ʒss.—M.

Under the use of this powder the vegetations, even when quite large, decrease rapidly in size until they can be attacked with the knife.

OXIDE OF ZINC IN DIARRHŒA.—The following formula is recommended in mild cases of enteric disturbance:

℞ Zinci oxid., ʒiiss;
Sodæ bicarb., ʒss.—M.

Div. in chart. no. xii.

Sig.—One every second hour.

IN HEMICRANIA.—

℞ Quiniæ sulph.,
Acid. tannic., āā gr. xii;
Aconitiæ, gr. $\frac{1}{4}$.—M.

Ft. in pil. no. xv.

One to be taken daily, or oftener if necessary.

CALOMEL OINTMENT FOR CHANCRES.—M. Mauriac, at the Hôpital du Midi, Paris, uses in cases of infecting chancre the following dressing:

℞ Hydrarg. chlor. mit., ʒii;
Cerat. simplicis, ʒi.—M.

If the chancre is inflamed, a few grains of extract of opium may be added.

USE OF CODEINE IN BOULIMIA.—Dr. Emminghaus has used codeine with success, in the dose of one-tenth of a grain three times a day, in diabetes complicated by boulimia. The latter symptom, after four days' treatment, entirely disappeared.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, NOVEMBER 21, 1874.

EDITORIAL.

ONE BATTLE WON.

A LITTLE over a year ago, when the *Philadelphia Medical Times* first began its onslaught upon the Philadelphia Hospital, nothing seemed more unlikely than that any impression should be made upon the flinty hardness of those abuses which had slowly crystallized during a quarter of a century. Many were the complaints that came to our editorial sanctum,—complaints whose burden was that the *Times* was simply laying bare to the gaze of the world the plague-spots of our community, and that no real good, but only ill repute, could come out of such procedure; or, in other words, that the *Times* was needlessly and uselessly disgracing our city. Unmindful of censure, we have continued the course first marked out; but it is with a feeling of real thankfulness that we to-day inform our readers that the contest is essentially over,—that the Board of Guardians have not only practically acknowledged the need of all the reforms we have demanded, but have also set themselves earnestly at work to achieve results.

We do not desire to arrogate to ourselves in this matter, but we know that the various editorials alluded to have attracted much attention, and that they awakened a wide-spread suspicion that the Philadelphia Hospital was a disgrace to our city.

In any case, so that the desired reform be achieved and the misery be relieved, we have long since ceased caring who gets the credit. We would, indeed, not have mentioned the connection of this

journal with the subject, had it not been for the fact that some of our editorials upon the medical schools of this country have given rise to angry comments precisely similar to those we have heard so often before. "You are simply ruining us abroad, and you won't do any good at home," said a venerable, but not well-pleased, professor, a few days ago; whilst others have taken up with great inward satisfaction the cry of "Ishmaelite," a name which can have no true application except in the fact that the editors of the *Times* are ready to attack any abuse within their province, no matter what interests are at stake, and no matter how smoothly age and respectability may have stuccoed over the rottenness.

In the United States public opinion is omnipotent, and the people for the most part honestly desire to do what is right in matters of public interest. To convince the people that any existing custom or institution is a curse instead of a blessing, or is even essentially unjust and wrong, is to make the great step towards reformation. We have the profoundest faith that at some not far-distant day, when the system of medical education now in vogue has been long enough in the pillory, its present supporters will be the loudest in asserting, "We always have been advocates of reform."

As a warning answer to those who now misuse that good old proverb about fouling one's own nest, and not betrayed by any spirit of self-gratulation, have we been led into these words of self-defence. We trust our readers will pardon our occupying that space which might perhaps have been better employed in discussing details of the proposed changes which will undoubtedly be hastened by the recent long-predicted but most opportune murder.

We use the expression "most opportune murder" advisedly. It has long been predicted that crowding lunatics at night into small apartments without attendants would eventually lead to such fatal result as has recently happened,—one lunatic murdering another without let or hindrance; murdering him opportunely, because it is better that one should die than many,—better that a single outbreak of violence should put an end to the steady conversion of curable into incurable insanity, the steady destruction of all the remaining glimpses of reason and of all the sense of decency in the partially insane, the slow crowd-poisoning and crowd-torturing of the hopelessly crazy, the gradual obliteration of everything human, and the *pari passu* development of everything brutal—all of which are the present daily routine in the Insane Department of the Philadelphia Hospital.

CORRESPONDENCE.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

AFTER hearing Dr. Gross's address before the Public Health Association the other night, I asked myself, "Are general hospitals, as heretofore and as at present constituted, pest-houses and abominations, the direful spring of woes unnumbered, or are they blessings?" The next day I searched for, and found in my office, the last two annual reports of the Board of Managers of the Pennsylvania Hospital to its Contributors, and, taking that of 1873, I made some approximative statistics. On showing them, however, to some of my friends, Dr. Ashhurst very properly said that they would not do to use before the Association, as they could be picked to pieces for want of definiteness. This statistical business takes time, Mr. Editor; but Dr. Woodbury, of the hospital, was so kind as to go over the record for me, and the results were still more surprising to me than my rough estimates. I did not get the paper until the third afternoon of the meeting. The session was fully occupied with other business, and I left the statement with my friend Dr. Le Conte, who said he would get it in if possible. It was simply an unvarnished summary of the mortality of the Pennsylvania Hospital for the year 1873. The year was not selected. I had intended to go over the last two years, but time prevented, and the work was great. It is often, however, a subject of remark how much one year is like another; and when we have the fact that the yearly mortality of the hospital from its very beginning ranges from eight and a half to ten per cent., I think nothing is wanting to establish my statements.

See, then, Mr. Editor, the record of the oldest "pest-house" in America (now well advanced in its second century) for the year 1873:

Summary of an Analysis of the Surgical Mortality of the Pennsylvania Hospital for the year 1872-3:

Whole number in house, 2155; of whom there died 172, or 8.59 per cent. Of these cases, 1387 were surgical, and 768 medical.	
The whole number of surgical deaths was	90
Of these, there died within twenty-four hours, that is, were killed by the accident for which they were brought to the hospital	35
There died in 2 days	7
" " 3 "	4
" " 4 "	1
" " 5 "	2
Of troubles essentially fatal, as spine- and brain-injuries, burns, wounds, etc., there died in periods from 6 to 93 days	9
There died of cancer	3
" " tetanus	2
Cases fatal in themselves, in or out of hospital	63
Leaving a mortality of	27

to account for, of whom 4 are put down to pyæmia. The others were made up of very severe cases, such as compound fractures, exhaustive suppurative troubles, necrosis, etc., etc., and it is certainly fair to presume from the social status of most of them that their lives were prolonged and their sufferings were ameliorated as well within as without a hospital.

Query: How many died of hospitalism?

Now, Mr. Editor, think of it: all will certainly agree that the thirty-five one-day cases should be eliminated altogether from the consideration of the mortality. The hospital, as a hospital, had nothing to do with the death of the remainder of the sixty-three, and as for the twenty-seven, there was enough to kill them in themselves, without going to hospitalism to account for it, except, may-be, the four pyæmia cases. I question whether in thirteen hundred and eighty-seven surgical cases, mostly very serious, in private practice, four cases of pyæmia would not occur; and I am very certain of it, if the thirteen hundred and eighty-seven had been treated in the places where they lived. Think of the material that this hospital gets within its walls,—that, ranging from the essentially fatal ones, we have to treat those of all grades of severity,—and you have a full justification of your statement made a short time since, that, for its size, it is one of the most active hospitals in the world. No one is more surprised at the record than I am myself.

I wish to write a readable article, not burdened with statistics, but remember, I have the records of all, and I enclose you the list of the forty-nine who died during the first five days, if you choose to use it, to give some idea of the nature of injuries we have to deal with outside of this fatal line. As I have sometimes expressed it, the work we have to do on some black days is truly appalling. The list is as follows:

1, compound fracture of skull, 5 days in hospital; 2, burn, 1 day; 3, burn, 2 days; 4, burn, 1 day; 5, compound fracture of both femurs, 5 hours; 6, fracture of spine, 1 day; 7, contusions of trunk, etc., 1 day; 8, burn, 1 day; 9, cut throat, 2 days; 10, compound fracture of humerus, 1 day; 11, laceration of legs, 1 day; 12, contusions of body, 1 day; 13, fracture of spine, 1 day; 14, lacerations of legs, 1 day; 15, fracture of scapula and contusions, 1 day; 16, fracture of ribs and legs, 1 day; 17, compound fracture of both legs, 1 day; 18, contusions of trunk, 1 day; 19, gunshot wound of chest, 4 days; 20, tetanus, 1 day; 21, fracture of skull, 1 day; 22, fracture of clavicle and ulna, and contusion, 2 days; 23, concussion of brain, 2 days; 24, lacerations and contusions, 3 days; 25, rupture of urethra, 3 days; 26, fracture of spine, 1 day; 27, compound fracture of both legs, 1 day; 28, compound fracture of thigh, foot, and arm, 2 days; 29, burn, 1 day; 30, contusion of head, 1 day; 31, compound fracture of leg, 1 day; 32, laceration of head, 2 days; 33, compression of brain, 1 day; 34, compound fracture of humerus, 1 day; 35, fracture of skull, 5 days; 36, compound comminuted fracture of femur, 1 day; 37, gangrene of leg from ulcer, 3 days; 38, burn, 2 days; 39, compound comminuted fracture of femur, 1 day; 40, compound comminuted fracture of femur, 1 day; 41, burn, 1 day; 42, fracture of pelvis, 1 day; 43, compound fracture of leg, 1 day; 44, fracture of skull, 1 day; 45, burn, 1 day; 46, burn, 1 day; 47, strangulated hernia, 1 day; 48, fracture of leg, Bright's disease, serous apoplexy, 3 days; 49, compound fracture of both arms, 1 day.

I wish to be exact, also, and must state that in the

printed report there are ninety-four surgical deaths. Dr. Woodbury did not make up this statement, and could only find ninety on the books. This may arise from the former clerk including other days, or it may be an error. However, I will, if you choose, let the four go with the twenty-seven, and our record will not suffer much. Again, the report is not from January to January, but is from April 27, 1872, to April 26, 1873; but I have called it the 1873 report, as being read in that year.

So much for specific details. I cannot help thinking that this matter of hospitalism has been very much overstated of late. That there are preventable causes of mortality in almost all general hospitals, I have no doubt. That a *well-managed hospital*, of whatever construction, necessarily contains elements of fatality in the material of that construction or in its form, I very much question.

I am in favor of the study of construction and management in all directions, in order to obtain the best results; but I protest against high authorities giving the weight of their influence in such a way as to favor popular prejudice against what, so far at least, are among the best institutions of the land. If what some say in regard to these institutions is true, every willing hand should withhold his contribution, and every bequest or legacy now standing in a last testament should be revoked.

The ideas that a layman would get of hospitals from hearing and reading about hospitalism are, it appears to me, very analogous to the notions he would get of insane-hospitals through the authority of Reade's "Very Hard Cash."

Imagine a dictator, say, of the United States. Herefore not having paid any attention to the subject, he by accident reads the famous novel. In righteous wrath he rises and issues a decree to free the inmates of all the insane-hospitals, to burn the buildings to the ground, and to hang all the Kirkbrides and Rays in his empire. And he would be right, if the novel were true; but it is not. Who that thinks about it does not know that if there is one thing that proves there is an advance in culture—one thing that proves there is, after all, humanity in man—it is to be found in the present treatment of the insane as contrasted with that of bygone years?

The layman's opinion of a hospital is very much influenced by what he may happen to see or experience on a given visit.

Let him be one of a committee, for example, going through the wards when there happen to be no very offensive cases. He will be delighted, and will report everything lovely in that institution. But in a short time another committee reports that a certain ward is very foul, and that the institution is badly managed. Our friend is surprised; but if he inquires he will find that a bad burnt case, or one of traumatic gangrene, has come in since he last went through, and in spite of everything it will make some smell. It can't be helped. Some of my friends will smile at my bringing in here

my favorite illustration. We all know that a dead horse in an open field, with all the winds of heaven blowing about it, will contaminate the air for a certain distance in spite of the *perfect ventilation*, and make it unbearable for any ordinary human being.

Now, what is a case of gangrene, or one of bad burn, in so far as the sloughing dead parts are concerned, but a mass of carrion, the same as portions, as it were, of the dead horse?

If, then, by our arts we can make the emanations from such cases reasonably bearable, so as to be able to administer to the needs of the poor sufferers, should we not be pleased at our efforts, while we study to make them still more perfect? Don't have such cases, you say, in the wards. That is just one of the questions. They must be somewhere. If we crowd them together, most or all of them will die, and may-be their attendants also. We must remember that, with the exception of the dead parts they are trying to get rid of, they are living bodies with immortal souls. Therefore some of us approve of scattering them; and I have no doubt this plan gives the best results. I do not like the idea of a special ward for such cases in the main building, for in time it will become a pest-ward indeed. For this class of cases, on account of the general comfort, I should advocate an out-ward for temporary purposes *until the sloughing stage is over*; then I would remove them and distribute them in the main wards.

Many cases of sickness and death are put down to hospitalism, that are really cases by direct exposure or contact, and the hospital, as a hospital, has nothing to do with them whatever. In the first volume of the Pennsylvania Hospital Reports I give an account of how I myself have been poisoned three several times by the inhalation of noxious gases from human beings. The first was through a post-mortem case; the second, one of private practice; and the third only, a hospital-patient. Here, I was thoughtless of myself. Here, I experienced to the full that it is not that which goeth into a man, but that which cometh out, that defileth. My knife went into a huge gangrenous abscess, and out rushed the most terrible gas that it has ever been my lot to encounter. That cost me many weeks of sickness; but what had the hospital to do with it? Why, that man would have poisoned me if I had stuck him in the Tip Top House of Mount Washington, with all the windows open; and Old Probabilities would have been struck dead on the spot.

I do not intend to enter upon the endless subject of construction; of its great importance there is no doubt. Much is to be said on all sides; and, with thorough attention to a few radical principles, the purposes for which any given institution is wanted, and the space and funds that it has to carry out its object, will regulate the structure.

Miss Lees, when she was here, is said to have made the remark that she was astonished that we seemed to have thrown away all the lessons of the war. I think she is mistaken, and that it is not absolutely necessary to have a wooden pavilion in which to carry out those

lessons, but that all of us who had anything to do with those days have learned to treasure our experience and also to apply it.

I hope, Mr. Editor, I have been fully understood. I by no means claim perfection for the Pennsylvania Hospital, for in it I know we have much to attain. But when we consider the nature of the cases that come into it, and the fact, I believe, that an annual mortality of two per cent. is considered as indicative of a healthy condition of a large community like our city, what has so-called *hospitalism* to claim in the institution under consideration, when, excluding the thirty-five killed outright on the first day of their casualty, and yet honestly put into the table, we can sum up a mortality of but 4.8 per cent. for the remainder?

The hospitalism that inculcates strict attention to every detail of administration I believe in. The hospitalism that incites popular prejudice against magnificent charities, and that sees pestilence in the structure, from the chimney-pot to the foundation-stone, I utterly condemn; believing that what is wanting is less hospital on the brain and more brains in hospital.

AIX-LES-BAINS, October 14, 1874.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—I have not yet heard whether it is proposed to hold an International Medical Congress at Philadelphia in 1876. The occasion would be a very favorable one, and if it should be decided to take advantage of it, it would be in conformity with the wish expressed by the physicians who attended the Congress at Florence, that in future there should always be a reunion of the medical world in every city where an international exposition should be held. During this Congress the United States were represented by Dr. Pinckney, of Boston, but he had, perhaps, quitted Florence before this wish was expressed. If it should be deemed advisable to hold this International Medical Convention, it is now time to decide upon the list of questions which shall be introduced for discussion, and to make them known throughout Europe by means of the medical journals. At the Congress in Florence, in 1869, there were two meetings each day, morning and evening. In the morning those subjects only were discussed that were indicated on the printed list; in the evening, opportunity was given to introduce any new question that any one desired.

If I might be permitted to make a suggestion, I would ask that the question should be discussed which has never yet received a satisfactory solution,—viz., that of the origin of fermentation.

1. Do the germs of fermentation exist exclusively in the air?
2. Do they not exist in the organism of human beings? and, if so, are they brought there by the air, or engendered by the vital forces?
3. Are the germs of fermentation engendered spontaneously?

Accept, sir, for yourself and for the faculty, the expression of regard and esteem with which I remain

Yours truly,

C. MACÉ,

Physician at the Baths of Aix and Marlioz in Savoy.

PROCEEDINGS OF SOCIETIES.

AMERICAN PUBLIC HEALTH ASSOCIATION—THIRD ANNUAL MEETING.

FIRST DAY, TUESDAY, NOVEMBER 10, 1874.

THE Association was called to order about noon. Upon taking the chair, the President, Dr. Stephen Smith, of New York, made an address, briefly reviewing the progress of sanitary studies, investigations, and administrations during the past year. He alluded to the labors of the Executive Committee of the Association in preparing the various papers read at the last annual meeting, the result of which was before the Association in the shape of a volume which, in literary and scientific merit and in typographical execution, has no superior in sanitary literature. The President went on to allude to the various epidemics prevalent in different parts of the world during the past year, which had, on the whole, been an exceptionally healthy one. He regretted that the United States Government had not been represented at the recent very important meeting of the International Sanitary Conference at Vienna. The progress of sanitary organization in the United States has not, during the past year, been satisfactory, Maryland being the only State that has organized a State Board of Health, which is the seventh now in existence. In New Jersey, a Commission of Health has been appointed to report upon general sanitary questions. There are now two hundred local boards of health in the United States, and in these it is evident that there has been an improvement in membership,—the medical element having become stronger. The effort made at the last session of Congress to obtain sanitary legislation resulted in such a manifestation of interest as to give rise to the hope that at no distant day such co-operation on the part of the general government might be secured as would lead to the perfection of sanitary organizations for defence against foreign epidemics, or the control or suppression of domestic pestilences which have a national character and importance.

An address of welcome was then pronounced by Prof. Henry Hartshorne.

At the close of this address, Prof. Hartshorne proceeded to read a carefully-prepared paper on "*Excessive Infant Mortality in Cities.*"

Among those born with a normal constitution and under entirely favorable circumstances, the mortality during infancy and childhood ought to be less than at any other period of life. Yet the reverse is the case in many localities, most notably in large cities. In France, according to Bouchet, one-sixth of all born die during the first year of life; in Sweden and Finland, one-fifth; in Prussia (Berlin), one-third. Nor is the proportion very much less in some parts of England and in this country. Looking back through considerable periods, we find that in 1810, in New York, one-half of all the deaths took place in persons twenty-four years old or upwards; in 1857, one-half the deaths were of children not more than two years old. In Philadelphia, in 1807, half the deaths occurred after twenty-four

years of age; in 1856, one-half were of children less than four years old. These last figures show an *increase* of mortality, relatively, at least, among children.

Dr. Farre has shown that in London it has been otherwise. The mortality of that city, which, about the middle of the eighteenth century, stood at seventy-five per cent. of children under five years of age, had fallen at the beginning of the nineteenth century to fifty per cent., and now about twenty per cent. die during the same period. The rate has been declining a little during the past few years in New York and Philadelphia.

The causes of excessive infant mortality may be comprehended under two heads: *ante-natal* and *post-natal*. Under the former head may be included constitutional defects in parents, resulting chiefly from alcoholism, syphilis, scrofulosis, debility from overwork and under-feeding in the poorer classes; in those more prosperous, excess of nervous temperament and deficient organic development in women who become mothers. As regards the latter point, it might be safer to include men as well as women. Both run to brains and nerve too much in this country.

Post-natal causes of infant mortality differ in different climates. Northern cities lose many infants in the winter by pneumonia, capillary bronchitis, and croup, under the exposure to cold so often connected with poverty and neglect. Dr. Farre has shown that in London the degree to which the thermometer descends in December, January, or February, determines, to a great extent, the mortality of the winter.

Sir Thomas Watson asserts the mortality in England to be always larger in winter than in summer, unless under the influence of occasional epidemics. This last observation will not hold true of our large cities in this country. Nothing in our mortuary statistics in Philadelphia and New York is more constant than the proportion between the number of deaths among young children and the excess of the daily temperature above 95° Fahr. in the shade; indeed, we might safely say above 90°.

Along with this positive cause of disease taking effect most severely upon the infant population, must be apprehended and remembered also the action of impurity of atmosphere. The great importance of this latter as a factor in the mortality of infants in large cities has been fully recognized in times past. There seems to be some ground for fear that it may be at the present time too little borne in mind under the almost overshadowing attention given to another factor, itself truly of great consequence,—bad feeding of children.

Errors in infantile diet may be considered as they occur: first, when the child is suckled in part or altogether by the mother or a substitute; and second, when it is fed entirely by hand or with the bottle. The evils of neglect, early weaning, or abandonment on the part of the mother, are exemplified in the practice of baby-farming as carried out in France and elsewhere, and in a more intensified form in the frightful mortality of foundling-hospitals.

Dr. Hartshorne went on to speak at some length upon the varieties of food suitable for infants, and the care necessary in preparing it, and alluded in terms of praise to the pamphlet of directions published by the Philadelphia Obstetrical Society a year or so ago.

The diseases especially destructive to young children are, in the great cities of the Northern United States, cholera infantum, smallpox,—where vaccination has been neglected,—cerebro-nervous disorders, with convulsions, pulmonary inflammation, croup, diphtheria,—when the latter is epidemic,—cerebro-spinal meningitis,—when it is locally prevalent,—and scrofulous marasmus.

Now, what can be done to lessen this truly frightful array of influences hostile to infantile life and health?

To meet ante-natal deleterious causes connected with parentage, we must look chiefly to popular education, moral reform, and sanitary police. Against post-natal causes of infantile mortality similar measures will be of great importance: children's excursions in hot weather as at present practised, and, perhaps above all, the provision of summer-camps outside of large cities, for mothers with young infants.

Not only would the direct rescue of a large number of infants—perhaps five hundred in this city—be accomplished, but such camps would also be training-schools in healthy living to all who occupied them, the effects of which might last long afterwards. Moreover, by the removal of a part of their population, the worst quarters of the cities so relieved might be open to inspection and effectual permanent compulsory sanitation. So the tenement-houses of New York, in which half of the population of that city are born, and of whom probably half die in their first year, and the Alaska Street shanties of Philadelphia, might be and ought to be abolished, and in their place might grow up homes for working-men in which children might not only be born, but live as well.

Dr. J. R. Black, of Newark, Ohio, then read a paper "*On the Influence of Hereditary Defects upon the Health of the People, with suggestions in regard to Prevention and Eradication.*" He remarked that the prevalent idea among many worthy people, that afflictions and sickness are brought on by some higher power, resulted in hospitals and asylums for the *cure* of disease, while all purely mundane efforts to prevent its causation were neglected and scarcely considered obligatory in a public or personal sense.

After alluding to the gradual development of hereditary tendency to disease into disease itself, and the resultant transmission of the same, the speaker went on to state that of late the achievements of science have actually tended to produce an increase in the number of physically degenerate men and women by interfering with the natural law of the "survival of the fittest."

In conclusion, Dr. Black's suggestions in regard to prevention and eradication would include proper attention on the part of the general public to the conditions of good health.

Avoidance of impure air, of confinement to dark and especially damp rooms, and of improper clothing and food, with the regulation of marriage, were to be recommended. In fine, precisely that which prevents sickness will also prevent the stamping of an inherent defect upon the organism.

At the conclusion of Dr. Black's paper, Dr. J. G. Richardson, of Philadelphia, read a short extract from a lecture delivered by him at the University of Pennsylvania three years ago, in which, while speaking on this subject, he had alluded to the probable existence of a law the opposite of the "survival of the fittest," which he had at that time formulated as the extinction of the unfit. After some remarks by the Rev. Dr. Osgood, of New York, on the moral aspects of the subject, an abstract of a paper by Dr. Edward H. Janes, of New York, "*On the Health of Tenement-Populations, and the Sanitary Requirements of their Dwellings,*" was read by the secretary. The Association then adjourned until 3.30 P.M.

At the afternoon session, a paper was read by Dr. H. B. Baker, Secretary of the State Board of Health of Michigan, entitled "*A Report upon the Death-Rate of each Sex in Michigan; and Comparison with Dr. Farre's Life-Tables of Healthy Districts of England.*" This paper was illustrated by means of carefully-prepared diagrams, and accompanied by various statistics. The relative mortality of the different sexes was shown to

be about the same at all ages, no climateric influence showing itself in females. A comparison of deaths per 1000 of population in England and Michigan showed the percentage about the same up to the eightieth year, subsequent to which the difference was in favor of the latter.

Dr. I. S. Billings, Assistant-Surgeon U. S. Army, then read a paper entitled "*Notes upon Hospital Location and Construction.*"

After alluding to the various reasons which led to the erection of hospitals, political, social, etc., the speaker went on to say that experience has shown that large and costly hospitals, even on the pavilion plan, are not necessarily free from the evils indicated by the word "hospitalism;" and a practical trial in our late war, repeated and confirmed more recently in Europe, has led to the recommendation that hospitals should be temporary wooden structures, intended to last but ten or twelve years. The good results obtained in our large military hospitals were not alone due to their temporary character, for the morbid element due to length of occupation did not have time to develop in them. They were better located than civil hospitals, being in the country, where there was plenty of room and fresh air. The class of patients was better, the control over them more efficient, and they were more readily classified, than in civil life, thus lessening the evil of placing a number of men in one room with different diseases and wants.

When cases of zymotic disease occurred, tents were largely used; and the more they were employed the better the result. In an economical point of view it is evident that if one-half the money required for brick or stone structures was used to erect plain balloon-frame wooden buildings, and the other half were invested at ordinary rates of interest, at the end of about twelve years the amount of money on hand would be what it was in the beginning, and the old buildings could be removed and the process repeated, thus giving a new hospital every twelve years. The necessary buildings for the cure of two hundred patients should be constructed for about \$50,000. The smaller the number of patients, the greater the cost per bed. Our large metropolitan hospitals usually are, and should be, connected with medical schools, and on account of accessibility it is generally considered necessary to place them in or very near the city, where space is limited and costly. Dr. Billings doubts very much whether this supposed necessity exists, and whether it would not be possible to place hospitals five or ten miles away from the city, where they could have ample space, and place the medical colleges with them.

Many special advantages pertain to floating hospitals, a class of structure of which more use should be made.

Such hospitals might be constructed on flat-bottomed boats radiating from a central triangle or polygon, any one of which might be detached and floated off if at any time there was such a necessity.

Such a hospital could be most conveniently arranged for three hundred beds or less, and, where space can be more conveniently obtained on water than on land, would serve an excellent purpose; but the temporary character of the structure must be insisted upon.

When, from the necessities of the case, a hospital must be built in the city, brick may be used. The laundry should be located at the top of the administration building, by which means an important aid to ventilation would be gained in the sources of heat which must constantly be connected with this portion of the establishment. This arrangement has been adopted in one of the recently-built army hospitals.

The materials which should constitute the inner walls are of the utmost importance. The plaster with which they are frequently lined is not of as good a character

or as hard a finish as is desirable. They should be cleansed, not by washing, but by burning, which may easily be accomplished by the use of a large smokeless flame. Twice a year plastered walls should be thoroughly scraped, and the plaster should be entirely removed at least every ten years. In certain army hospitals whitewashed canvas has been successfully made use of as a lining to the wards; of course this can be removed and renewed at pleasure. Cases of erysipelas should never be allowed in the wards of a large municipal hospital, but should be assigned entirely separate and distinct quarters. Puerperal cases should be treated in cottage-hospitals, or by some similar plan.

As regards ventilation, Dr. Billings considered fireplaces as useful auxiliaries, but hot air as better for general use. Of course, the best plan for changing the atmosphere of an apartment rapidly is to have the floor riddled with minute holes, through which the fresh air, warmed when necessary, may be introduced: in a hospital, however, this is impracticable.

It cannot be expected that the air of a ward can be made fresh by any means; the object is to dilute the foul air to the highest degree possible. Water-closets should be ventilated from below, and their ventilation, as well as that of bath-rooms, should be entirely separate from that of the wards.

Hundreds of books have been written on hospital management, and the subject has been considered from every possible point of view excepting that of the patient. As wards are at present arranged, there is absolutely no privacy. There is also too much light for many cases; we have but to put ourselves in the position of the patient a moment, to see how trying this must frequently prove.

There is, besides, too much sameness in temperature and moisture: a temperature which is exceedingly grateful in one case must be very trying in another. There should be smaller rooms and more privacy, if possible.

In the model hospital of the future, one-, two-, and three-bed wards will be used, except for the convalescent. Special beds will be provided, having funnels suspended over them; in such a bed the patient is entirely isolated, and even where profuse suppuration or gangrene is present the surrounding air will remain uncontaminated by any odor. Above all, however, good superintendence is necessary.

Dr. William Pepper, of Philadelphia, followed with a paper "*On the Sanitary Relations of Hospitals.*"

After some remarks on the late Sir James Y. Simpson's views on what he denominated "hospitalism," Dr. Pepper went on to allude to the present drift of opinion in favor of barrack-hospitals. After referring to the frightful mortality which has been observed in many large hospitals, owing in great part to the prevalence of such diseases as pyæmia, he stated it to be his belief that this result depended not essentially upon the mere fact that the hospital was a large, permanent structure, but upon the existence of remediable faults in construction or of abuses in administration. The arguments which have been adduced had failed to convince him of the propriety of tearing down many of the large "palatial" hospitals in existence, or of avoiding the construction of similar structures in the future, but had only shown the necessity of remedying certain defects of construction and of sternly repressing certain abuses of administration.

Among these abuses may be mentioned overcrowding of patients, or placing too many wards on a limited area of ground. In connection with this subject, the case of the Norwich (Eng.) Hospital may be mentioned. This hospital, up to the year 1862, maintained a high reputation, in support of which it may be mentioned that its records up to that period showed a percentage of cures

in the operation for stone almost unprecedented; the proportion of fatal cases in a long series being but one to eight and a half. In one series of forty cases, no death had occurred.

But since 1862 this hospital has been overcrowded. During the ten years from 1854 to 1863, 2200 cases were treated, while during the subsequent decade from 1864 to 1873 3800 of the same classes of patients, including cases of burns, fractures, and surgical cases generally, were treated. Mark the result. A frightful increase in the mortality took place; the institution, which had been celebrated for its success in the operation for stone, now showed a rise in the proportion of fatal cases from one to nearly nine up to one to seven.

The conclusion to be drawn is evidently that so long as the number of patients in the hospital was kept within the proper limits all was well, and that overcrowding alone brought about this lamentable result.

But the avoidance of overcrowding is not all that is necessary; certain wards should always remain closed and in reserve, only to be occupied when the other wards are not in use. A well-built hospital of permanent construction can be purified or renovated thoroughly, and far more cheaply than a barrack-hospital can be destroyed and reconstructed. In the Pennsylvania Hospital it has been the custom, when pyæmia has appeared in any ward, that that ward should be thoroughly cleansed and vacated for months, and the result has been that on reopening it no pyæmia has appeared. In the medical wards of this hospital no epidemic has ever prevailed, with the exception of a mild form of facial erysipelas from time to time.

Dr. Pepper went on to give his views as to the proper method of keeping a large hospital healthy. Among other arrangements he suggested the use of isolated apartments or separate isolated barracks or tents of purely temporary character for cases of erysipelas, gangrene, extensive burns, and the like, as well as for patients affected with dysentery or one of the contagious fevers.

He also described the general plan and arrangement of the new Hospital of the University of Pennsylvania: a large structure built on the pavilion plan, with central administrative building and lateral pavilion connected by means of a corridor; in whose arrangements every care has been taken to avoid all the sources of difficulty observed in many large hospitals.

Continuing with the general subject of hospital management, the speaker said that it is the duty of every city to supply ample hospital accommodation, but, in consideration of the enormous sums required for their proper administration, the construction of the hospital should be with as strict a regard to economy as is consistent with efficiency.

Hospitals should not be too far from the centres of population, in order that the services of the best medical men should be secured. If placed at such a distance from the heart of a city as to secure the advantage of cheap land, it would be too far away to secure the gratuitous services of leading physicians, and a salaried medical superintendent or staff would have to be supplied, with results which are familiar.

If, on the other hand, a large hospital is built where land is dear, the plan of isolated temporary barracks can scarcely be made use of. Moreover, if barracks of a permanent character, of brick and stone, are erected, not only are they liable to become infected just as the wards of a larger permanent structure, but it may be doubted whether the cost of construction per bed would not be as great as in the latter case. If the greatly increased cost of a site, together with the great increase in the cost and difficulty of administration, be taken into consideration, the enormous practical difficulty of replacing the present hospital-accommodations of great

cities, such as London, New York, or Philadelphia, by "iron, wood, or brick villages" becomes evident.

A further great advantage of a large hospital is the aid which it affords to the prosecution of clinical instruction: it is difficult to transport cases from the widely-separated wards of a building on the barrack plan.

It is a question of importance whether the bad results attributed to large hospitals are necessarily connected with the permanent plan. Unfortunately, there are no statistics in existence which can aid us in coming to a conclusion. What is wanted is a comparison between the results obtained in large well-constructed and well-administered hospitals in the centre of great cities and those furnished by barrack-hospitals in the same locality, receiving the same run of patients and employing the same modes of treatment. Until this point is established, it is certainly more rational to endeavor to remedy, as can be shown to be practicable, the defects of construction and administration of large hospitals, than to destroy public interest in their support by decrying them as slaughter-pens and curses to a community.

In conclusion, Dr. Pepper remarked that the physicians constituting the medical staff of a hospital are not the proper persons to regulate its sanitary condition. They are too much engrossed in the cases, and too prone, in their desire to extend the benefits of the institution as widely as possible, to admit more patients to the wards than should properly be received.

A hospital whose governing body should contain medical men of experience, entirely unconnected with the staff, in conjunction with a certain number of business-men, would offer the correct method of administration.

Dr. Pepper was followed by Mr. Carl Pfeiffer, F.A.I.A., of New York, who read a paper on "*Hospital Architecture, and the Perfect Ventilation of Hospital Wards*."

Subsequent to the reading of this paper, a conference of sanitary officers and others upon methods and experience in the public health service took place.

The subject was introduced by Dr. Le Conte, late of the United States Army, who read a paper on the organization of municipal boards of health. This subject was discussed by other members of the Association, after which a recess was taken until evening.

At 7.30 P.M. a meeting of a more general character was organized, with the Hon. Morton McMichael in the chair. After a few opening remarks by this gentleman in his usual felicitous vein, the Rev. Dr. Samuel Osgood was introduced, and delivered an eloquent discourse on "*The Relations of Health and the Higher Culture*."

Prof. Samuel D. Gross then delivered an address upon "*The Factors of Disease, and Death after Injuries, Parturition, and Surgical Operations*."

This discourse, which was of considerable length, was principally occupied with questions relating to the proper management both of hospitals and of individual cases.

Various methods of after-treatment adopted by distinguished surgeons of this country and Europe were commented upon, and the conclusion arrived at that the most important point was perfect cleanliness, the particular dressing employed in any given case being comparatively a matter of indifference.

In treating of hospitals, the speaker stated that in most of them the mortality was frightful. He referred, however, to the Episcopal Hospital and to the Hospital of the University as presenting better features than most institutions of the kind, and as being well planned.

No single ward of a hospital should contain more than six or eight beds; and no hospital should accommodate more than one hundred patients. In conclusion,

Dr. Gross referred to the necessity of erecting convalescent homes or hospitals, where patients who had passed the crisis of disease could recover their strength without danger of infection from persons affected by other diseases.

On motion, a vote of thanks was unanimously tendered to Rev. Dr. Osgood and Prof. Gross for the instruction they had afforded.

The Association then adjourned, to meet at 9 o'clock on Wednesday morning.

SELECTIONS.

"LEGUMINOSE."

IN the *Berliner Klinischer Wochenschrift*, No. 15, 1872, appeared an article by Prof. Dr. Beneke, of Marburg, "On a Substitute for Animal Food for Convalescents in various Diseases of the Stomach and Intestinal Canal, and for Poor Patients." H. Hartenstein was induced by the above article, and following the suggestions therein contained, to prepare for sale, under the name of "Leguminose," a powder for making soup, composed of a mixture of leguminous and cereal meal.

In an article in the *Berliner Klinischer Wochenschrift*, No. 22, 1874, Prof. Beneke expresses approval of the Leguminose as practically fulfilling every indication for which it is intended. It has been established beyond a doubt, by careful chemical analysis, that meals of all kinds contain a large amount of nourishing matter, pure leguminous meal being not far behind beef in this respect. Being freed from any shreds of cellulose, and reduced to the very finest state of subdivision, this preparation has been made of extremely easy digestion. In addition to its highly nutrient properties and easy digestibility, its great cheapness should not be left unmentioned, the cost being only fifteen groschen (thirty-four cents) per pound, which renders it very useful as a diet for the poorer classes. By the admixture of cereal meal, also very finely divided, the proportion of nitrogenous to non-nitrogenous matter is made to vary, in the four different mixtures now in the market, standing respectively as 1 : 2, 3 ; 1 : 3, 3 ; 1 : 3, 9 ; 1 : 4, 8, thus being equivalent, in order, to the proportions found in beef, milk, breast-milk, and the mixed food of adults. It is shown, by most careful analysis, that the different kinds of meal contain 10 to 12.7 per cent. of water, whereas beef contains nearly 75 per cent. and cow's milk 86 per cent. One pound of fine meal contains, therefore, three and one-half times more solid constituents than meat, and more than seven times as much as cow's milk.

The method of preparing the soup for use is to stir slowly a heaping tablespoonful of the powder in a soup-plate of water, and then boil thoroughly for half an hour and add salt. The taste is said to be agreeable when thus carefully prepared, though, should any taste of the raw peas or lentils remain behind, a little Liebig's extract of beef can be added. When this disagreeable taste cannot be got rid of, it is suggested by Dr. Beneke that the quality of water with which the soup was made may have something to do with it, and that if it is very hard a little soda should be added.

As the percentage of fat in these meals is small; the non-nitrogenous elements being mainly represented by amylum, it is recommended, when fat is particularly indicated, as in atrophied children, consumptives, and convalescents, to add to the prepared soup one to two teaspoonfuls of cream. When, for instance, the proportion of nitrogenous to non-nitrogenous matter desired is 1 : 3, 3, Dr. Beneke employs mixture 1 (1 : 2, 3), adding the cream as above.

With regard to the objection which naturally suggests itself, that leguminous articles of diet cause flatulency, no mention is made by those who have used it of any such trouble having been produced, and it probably only occurs when the peas or beans are prepared in the ordinary way.

After the second year, the system requires a small quantity of vegetable acid or of salts containing it. As leguminose contains none, when this is used exclusively the deficiency should be made up by giving lemonade, compote, fruit jelly, or wine containing it. When the stimulating effect of animal food is indicated, this can be obtained by the addition of Liebig's extract of beef, rich in creatinine and the salts of potash.

Dr. Beneke, in his endorsement of the merits of the above preparation, is supported by equally favorable reports from a large number of physicians of respectable standing in different parts of Germany who have used it as an article of diet for patients with impaired organs of digestion, for infants deprived of the breast, where cow's milk is not well tolerated in any form, for atrophied and scrofulous children, for convalescents from typhoid fever, and for consumptives; also during the acute stages of disease, as of acute rheumatism and of typhoid fever.

Should it be made easily obtainable in this country, at a relatively cheap price, the leguminose would certainly merit a trial at the hands of the profession, with prospects of proving a very superior article of diet for infants and for the sick-chamber.—*Boston Medical and Surgical Journal*.

GLEANINGS FROM OUR EXCHANGES.

THE BLISTER-TREATMENT OF RHEUMATISM.—Dr. T. R. Peacock has used the blister-treatment, introduced by Dr. Davies, for acute rheumatism since 1865. He has a high opinion of it when vigorously applied. The blisters are generally made two or three inches wide, and long enough to encircle the limb. When they have risen, they are dressed with linseed-meal poultices for several days. Usually, the patients do not complain of the blisters, nor is there any serious inconvenience from them; but as soon as the drawing is accomplished there is a marked amelioration in the swelling, pain, and constitutional disturbance. The cases most eligible for treatment by this means are those where several joints are involved and the suffering and constitutional disturbance great. Three to six blisters are applied at once near the affected joints; they are repeated as exacerbations occur, and are applied to joints as they are successively involved.

Dr. Peacock agrees with Dr. Davies that this treatment often curtails the length of the disease and prevents internal complications. He regards the blisters as less depressing than the alkalies and other constitutional medication, except tonics, which he often gives.—*The Doctor*.

PUNCTURE OF KNEE-JOINT IN HYDRARTHROSIS.—Dr. Dieulafoy (*Memorabilien*, October, 1874) mentions twenty-two cases of fluid in the joints which were treated by Desprès sixty-five times by aspiration with no evil results. Some of the cases were cured in less than a week with one or three punctures, others in less than a fortnight with four or six; some in three weeks with many punctures. Desprès thinks, however, that ordinary treatment is quite as good in most acute cases, whilst in chronic cases of fluid in the joints aspiration is of great service. Other surgeons mention deaths as occurring from puncture.—*The Doctor*.

PREVENTION OF SEA-SICKNESS IN SHORT PASSAGES (*The Lancet*, October 10, 1874).—Dr. J. Henry Bennett believes that it is an error for travellers to go on board ship with a stomach full of food, and thus give it several hours' work to perform at the very time when it is disturbed and annoyed by the tumultuous motions of the vessel. To avoid exhaustion, a good meal should be taken four or five hours previously, but the stomach should be absolutely empty at the time of embarking. One or two hours before, some very strong coffee should be taken without milk. Once on board, repose in the recumbent position should be enjoined, and nothing whatever, solid or fluid, should be taken for twelve hours or more,—even then very little. On this system, food and a stimulant are taken *before* the stomach is exposed to sympathetic irritation, and the general economy and the nervous system are thereby invigorated. As there is nothing in the stomach to digest, it remains quiescent under difficulty.

ERGOTIN-INJECTIONS IN PROLAPSUS ANI (*Medical Press and Circular*).—Von Langenbeck, of Berlin, announces that he has lately been treating prolapsus ani "with astonishing success" by hypodermic injections of a solution of ergotin (five and fifteen parts to one hundred of distilled water). He replaces the bowel, and, inserting the point of the syringe about three centimetres in depth in the cellular tissue, throws in from one to two grains of ergotin. This should be repeated every three or four days for three or four weeks, any hard faecal masses in the bowels being first removed by simple injection.

CLAY EARTH AS A SURGICAL DRESSING (*Detroit Review*, October, 1874).—Dr. F. W. Godon gives a very favorable report of his experience in the use of the above dressing. Chronic ulcers intractable to all other modes of treatment healed rapidly under the application of dry earth. Open sores, wounds, etc., of great diversity, were successfully treated by the same. In burns and scalds he says that it most effectually and completely allays pain, produces cicatrization, controls inflammation, and prevents putrefaction.

CALABAR BEAN IN TETANUS (*The Medical Record*, October 15, 1874).—Philip S. Wales reports a case of traumatic tetanus unsuccessfully treated by Calabar bean. The patient died within two days after the onset of the disease.

MISCELLANY.

AN ORIGINAL INVOCATION.—When in 1837 the late Louis Agassiz pronounced his famous *Discours sur l'ancienne Extension des Glaciers*, at the Congress of the Swiss Society for Natural Sciences at Neuchâtel, he enunciated the theory that Switzerland was formerly entirely covered by a thick layer of ice,—a conclusion at which he, in common with other observers, had arrived in consequence of the striated and polished appearance of some of the rocks, and the evident removal of others. This was considered a frightful heresy; the whole assemblage was stupefied, until Leopold von Buch, one of the greatest geologists of the time, rose in much excitement, to denounce the new theory with unsparing severity. He was subsequently shown the striated surfaces near Neuchâtel, but still, not "convinced against his will," maintained that these appear-

ances had been produced by students sliding over the rocks, and finished by retiring abruptly from the scene, ejaculating, "*O sancte De Saussure, ora pro nobis.*"—*London Medical Record*.

"WILL you help me out of this mud-hole?" asked one traveller, whose team was stuck in the mud, of another who was passing. "No, I can't stop," said the other. "I would take it as a great favor," said the man in trouble. "What are you loaded with?" asked the traveller. "Patent medicines," was the reply. "I guess I will try to help you out, then, as I am loaded with tombstones." They have been constant companions ever since.

A NEW mineral has been discovered in South Carolina, which, it is said, contains enough phosphorus to supply the whole world for a million years.

A NEW YORK man has christened his daughter Glycerin. He says it will be easy to prefix Nitro if her temper resembles her mother's.

ONE of the latest "charms" for watch-chains is a piece of lunar caustic, handsomely mounted. It is found useful in cauterizing dog-bites.

AN instance of like curing like is mentioned in the fact of brandy being a certain cure for "staggers."

WHY is it impossible to have the last word with a chemist? Because he always has a retort.

TWENTY-THREE men graduated at Dartmouth Medical College, Hanover, N.H., on Nov. 4.

A STOMACH-PUMP is calculated to make a man feel down in the mouth.

BALTIMORE is to invest fifty thousand dollars in a botanical garden.

NOTES AND QUERIES.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—I notice by a recent communication to the *Times* that Dr. Weir Mitchell is inquiring for cases of chorea in the negro. As resident physician in charge of the Hospital of the Colored Home of New York, during the winter of 1855-6, I saw a case of true chorea minor in a mulatto girl about fifteen years old, which terminated fatally; but during an entire year of service there I observed no instance of the disease in either form in a pure negro.

Yours very respectfully,

BENJAMIN LEE.

Philada., 1503 Spruce Street, Nov. 4, 1874.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM NOVEMBER 10 TO NOVEMBER 16, 1874, INCLUSIVE.

HASSON, A. B., SURGEON.—Granted leave of absence for twenty days. S. O. 224, Military Division of the Atlantic, Nov. 12, 1874.

HARTSUFF, A., ASSISTANT-SURGEON.—So much of S. O. 233, A. G. O., c. s., as relates to Assistant-Surgeon Hartsuff, is revoked. S. O. 244, A. G. O., Nov. 10, 1874.

WILSON, A. D., ASSISTANT-SURGEON.—To report in person to the President of the Army Medical Board, New York City, for examination for promotion, and, on its completion, to the Commanding General, Department of Arizona, for assignment to duty. S. O. 243, A. G. O., Nov. 9, 1874.

SATURDAY, NOVEMBER 28, 1874.

ORIGINAL COMMUNICATIONS.

SANITY AND INSANITY.

BY N. ROE BRADNER, A.M., M.D.,

Late of the Pennsylvania Hospital for the Insane, Philadelphia.

AT the request of a distinguished member of the Philadelphia bar, I have devoted some spare moments to the consideration of a problem proposed for solution, and will say at the beginning that it is one uniformly thrust at medical experts in insanity, too frequently with undue consideration on the part of the legal questioner, although in this instance the writer well knows that the problem was proposed in good faith and after the subject had religiously received the questioner's own diligent consideration and study.

Insanity has been regarded as a kind of disease; and physicians, whose calling is the treatment of disease, have been largely consulted and interested in the subject, both generally and as to individual cases. If insanity is a disease, it is the only one which is not entirely intrusted to the medical profession. So uniformly is the name of the law associated with the subject, that in some forms and stages of the attack the sufferer's friends are uncertain whether to send for a lawyer or a doctor. Were it a subject easily comprehended by one proficient in either of these professions,—requiring of him little or no extra thought or skill,—it would matter not to which branch of learning the subject would fall heir; but, if it too often baffles the best efforts of each and both, methinks it were worthy of adoption by the joint powers of law and medicine, promising its guardians as it does abundant honor, even to two of the most honorable professions, when they shall have faithfully attended it through its own periods of incompetence.

It is yet a subject upon which there is a great diversity of opinion, even among men eminent in those professions, the researches of which should not leave it in perpetual obscurity. To define insanity satisfactorily—to propose a few words that would at all times and under all circumstances explicitly demonstrate just what insanity is—would be no easy task; but more difficult, if not impossible, would it be to accomplish the object of my friend,—to draw a line accurately dividing sanity from insanity, designating exactly the point where sanity leaves off and insanity begins.

I believe a more positive example than this of a uniform mistake made by legal gentlemen as well as by some physicians, in judging of the nature of insanity, is seldom made. If it were possible to set up a well-defined character truly labelled, "This, and nothing but this, is insanity," the converse would be no less practicable, viz., to designate a certain character as the type of perfection, and say, "This, and nothing but this, is sanity." Any one conversant with the vagaries of the human mind well

knows that a more absurd idea than this could not be invented, and that a character thus appointed, if it were that of a perfect man, invincible by any theory of insanity, would excel that of ninety-nine per cent. of all men. It is no part of the theory of psychologists that ninety-nine per cent. of all men are insane; but if any abstract line be drawn that would positively exclude every person amenable to a suspicion of insanity, and a power be established to declare to those who would be regarded as sane, "Thus far and no farther shalt thou go," certainly not one per cent. of us could pass muster. Now, this theory is all false; and it is a fact that will be well learned by him who seeks a true knowledge of the disease, whether medical student or jurist, that justly to decide the question of an individual's sanity he is not to be compared with any particular idol as the standard character of sanity, but with his own natural and normal self. Certainly, what would be insanity in one person is not necessarily so in another; and if this be so, a more unjust rule for judging of his sanity than that of the particular line could scarcely be conceived. It cannot even boast, we are glad, of modern invention, but looks back for its origin to Grecian mythology, and should be considered of the same relation to the scale of justice as the famous bed of Procrustes. Those who were so unfortunate as to lie upon the bed of this bold Grecian must correspond most accurately and literally in their length: if they were longer than the bed, they were too long, and their feet perhaps were chopped off; and if too short to fill the bed, they were sadly deficient in length, and were stretched out. In either case, the bed being the exact length allotted by Procrustes to man, its occupant's length must be made to correspond,—the deficiencies and superfluities of nature being thus summarily rectified. Truly, there can be no more justice in creating a standard mind than a standard stature; and we doubt if the prudent lawyer lives, no matter how often he may have attempted to confound a medical witness with demands for a particular gauge of mental soundness, who will not after due and careful consideration join with us and pray that the Procrustean view of insanity for which the legal profession has contended may meet with no favor in our age of enlightenment. These remarks have particular reference to those forms of insanity called doubtful or obscure, where, in the words of Dr. Bucknill, "its recognition is arduous in the extreme." "Ploughmen and blacksmiths," the same eminent psychologist has said, would be sufficient to decide when men were insane, if all cases were as plain as some. But, unfortunately, these plain and demonstrative cases are those of the only form of the disease recognized or acknowledged by a larger part of mankind. The public is reluctant to believe a man is insane unless, in the words of a worthy police-officer, "he is wild and raging, his eyes standing out, and his hair standing up;" and in the same measure there seems to be a distrust of medical experts whose observation and experience have enabled them to do all that has been done in this important and

difficult work. Nay, too often the opinion of blacksmith, ploughman, or other person wholly unacquainted with the subject is accepted in preference to that of the expert, although he may have devoted to and exhausted the best years of his life in its exclusive study.

In a recent court, a gentleman learned in his profession, and high in office, being asked if the person in question was insane, replied in the following words: "Of course he is insane: I am not one of those who consider it necessary to live five or ten years in an insane-asylum to tell whether or not a man is insane." The very next question put to him was concerning the condition of the urine in a certain form and stage of insanity; and what could he answer more or less than he did,—that he was not sufficiently experienced in the disease to be enabled to answer? This gentleman would scarcely have attempted to depreciate the experience of physicians in hospitals for the insane, as he did in his first answer, if he had known that he must so soon call such a one to his rescue. By just such examples as this it is often made apparent that the study of the mind, sometimes of a single mind, must be the work of time. The study of insanity, too, like that of nature, can scarcely be profitable except in the mode of practical observation. The man who has been blind from his birth can form but an imperfect idea of the beauties revealed by vision, and one without experience with insanity cannot correctly judge of the difficulty in deciding between some cases of sanity and insanity. The infirmity may be such as to be detected by the expert at the first interview, or so obscure that the most skilful physician may be uncertain after many and protracted meetings. True, it may be said that insanity so difficult of discovery may seem far-fetched; but it has been my experience that where insanity is discovered after having been so long concealed or disguised, it is most often a dangerous order of the disease, with promise of disastrous results. The importance, then, of a thorough, lengthy, and unobstructed inquiry into each and every question of obscure insanity cannot be overestimated by those desirous of arriving at a just and reliable decision; and now, as time advances, the necessity for an extended knowledge of this grave disorder is being more keenly felt, for, with a pace no less rapid than the course of time, insanity is growing and increasing upon us. It is, however, to those called the criminal insane that these remarks are intended to invite the especial consideration of thoughtful people, and I cannot allow this opportunity to pass without entering my protest against the unqualified name of "criminal insane" as applied to this class of sufferers.

It is just and humane that such a distinction should be made between the outrageous acts of those of sound and unsound mind, that the irresponsible shall be spared the punishment justly due the malicious criminal; but our enlightened humanity has but half expressed itself when, on the ground of insanity, we acquit the accused of crime and yet brand him "criminal insane." The outrageous acts of insanity, like those of infancy or

febrile delirium, are those of disease and incompetence, regretted most keenly by the unfortunate agent after he has become enabled to understand the nature of the act committed. True, murder is crime, but when an infant causes the death of another through his inability to comprehend the terror of death or consequence of the particular act of mischief, the child should not and forever be branded criminal; and surely where any act, no matter how terrible its character, is positively that of insanity, the unfortunate actor should be regarded with the same consideration with which we are constrained to look upon those of infancy. And, presto! while I write, the district attorney for this city has in his official capacity uttered a declaration, in but few words, that should add lustre to any name. In a murder-trial just closed, the defence of insanity being established, Mr. Mann boldly declared, "It was not this defendant, but a disease,—insanity,—that did the murder." Crime should be punished; insanity should be cured.

The physician and the lawyer should be as vigilant in protecting the insane from punishment as in demanding that a criminal shall be punished. Crime, too, is the real enemy of insanity; it is the wolf that knows the immunity of the proper kind of clothing; and hence the plea of insanity is a frequent one of defence in legal trials of supposed criminals. It is an awful responsibility that rests upon him who judges whether or not the plea is just; and it is here that the careful psychologist can often detect unmistakable proof of the disease even in one whose sanity had never before been questioned. Dear reader, your best brother may be as innocent of crime as the youngest babe, and a disease—insanity—may place him in the criminal cell before another sun has risen and set. If so, would you call upon ploughmen to investigate his mental condition? Ah, no! The most learned and skilful of psychologists would then be scarcely equal to your demands; but that host of mankind with whom you probably are now numbered would not believe in your suffering brother's insanity, unless, forsooth, he was roaring, furious, and uncontrollable. Should their clamor for justice result in a legalized execution of your insane brother, the barbarous act would not be the first, nor the second, nor yet the third instance of its kind for which American law and justice must blush in shame.

Let not the wicked escape the punishment their crime merits, however cunningly they may conceive and devise a defence of insanity; but doubly more let us be careful to avoid all legal murder of our insane.

And now a concluding query: How are we to distinguish between the acts of criminals and those of the insane? Space will not now admit of an anticipated review of the varying opinions expressed by those high in authority, both here and abroad, and the brilliant dictum of Dr. Isaac Ray alone will be quoted: "In trials of criminal cases, the single and only essential question is whether the act was or was not the offspring of disease." Thus did the eminent medical jurist strike the key-note of justice that should forever silence those discordant

theories that cry aloud for plumb and gauge where-with to measure each and every mind in comparison with their own particular Procrustean idol of sanity. True, it may be objected that the proposition of my venerable friend does not absolutely shorten the investigation, and the same lengthy observation of doubtful cases must still be granted to an expert before he can satisfy himself whether or not the individual is of diseased mind, or that his disease is the parent of any particular act. But why shorten the time? Why should not medical experts be allowed abundant time and opportunity for the most searching investigation into those cases, the facts of which they are expected to maintain against the most embarrassing opposition?

Need the course of justice be in any way diverted by postponing any trial until no reasonable doubt exists as to the mental condition of the prisoner?

In the State of Maine there is a law that whenever insanity is to be the defence in a criminal case, the prisoner shall be sent to the State Hospital for the Insane, to be observed by the medical officers until they are satisfied as to his mental condition. Of the first thirty persons thus observed at the hospital, six were found to be sane and twenty-four insane. Who is there to contend that the jails of our own proud State do not contain many poor victims of this terrible disease, unmercifully suffering in a manner prohibited in Maine for a quarter of a century?—nay, who are only awaiting the progress of the law to add their number to those who have suffered the full penalty of crime, and whose only crime is insanity?

OVARIOTOMY—SUCCESSFUL OPERATION.

BY W. H. MYERS, M.D.,

St. Joseph Hospital, Fort Wayne, Ind.

C. S., aged 36 years, residing in Leo, Cedar Creek Township, Allen County, Indiana; married nineteen years; mother of nine children, eldest eighteen years, youngest two years, one abortion. Emaciated; habits of life regular; surface of body cool; no glandular swellings of the loins; varicose veins on the right limb, without œdema of the feet.

The measurements on July 29, 1874, were as follows: Umbilical level, forty-one and a half inches; ensiform cartilage to the umbilicus, nine inches; umbilicus to symphysis pubis, nine and a half inches; from right anterior superior spine of ilium to umbilicus, eighteen and a half inches; from left anterior superior spine of ilium to umbilicus, nine inches. Mobility of tumor marked; evidence of adhesions on the right side. Over the abdominal surface dilated veins were numerous. Fluctuation decided; sounds on percussion, resonance on the left side, dulness on the right side.

The situation of the uterus natural; neck to the right; mobility normal; tumor projects; can be felt in the cul-de-sac. Womb-sound introduced into the cavity of the womb two and a half inches; rectal examination revealed nothing abnormal; catamenia, date of commencement, fourteen years; no sudden suppressions; cessation three months ago; urinary organs normal; occasional pain in the right hypochondrium; rests best on the right side. Signs of ill health began fifteen months ago; right limb weak, and also pain in the right

groin. She says she discovered the tumor in March or April, 1873. Enlargement rapid; first on the right side; not long until it became central.

April, 1874.—Dr. Woodworth and myself used the aspirator, and obtained an albuminoid fluid. From this puncture local peritonitis supervened, so that she was quite ill for nearly one week, and from it, we may infer, the adhesions originated that we encountered during the operation.

The diagnosis was made of a multilocular ovarian tumor, originating from the right ovary, and it was inferred from the rapid growth that life could be prolonged but a few months.

The patient was ordered good diet, baths, and iron, continued for several months, up to the time of the operation. Forty-eight hours before the operation she took one ounce of castor oil, and from this last period up to the operation one grain of opium every six hours. The morning before the operation her diet was restricted to gruel, and a simple enema was administered. She was dressed in flannel, with woollen stockings. A light gutta-percha cloth was placed in front of her, and through it was cut an opening sufficiently large to receive the tumor, and the edges fastened to the skin by a circle of adhesive plaster.

The operation was performed Thursday, August 6, at 2 P.M., at St. Joseph Hospital, Fort Wayne, Ind., in the presence of Drs. A. Woolley, of Warsaw, and A. D. Emmanuel, of Antwerp, and I was assisted by Drs. B. S. Woodworth, I. N. Rosenthal, T. P. McCullough, T. J. Dills, C. Lihler, H. V. Sweringen, I. N. Myers, E. L. Tons, James E. Moore, and F. Criswell. The patient having been etherized by Drs. I. N. Myers and E. L. Tons, she was brought into a small, retired, private ward, and placed upon a table, twenty inches wide and five feet in length.

A median incision about five and a half inches long was now made from the umbilicus to the pubes. Very little hemorrhage followed. Adhesions were found anteriorly, obliterating all traces of distinction between the walls of the tumor and the peritoneum. Discovering a point on the left side in the lower third of the incision where the adhesions did not exist, I was enabled to introduce a sound, No. 8, and with it to easily break up all adhesions in front, and then liberate the bond of union between the peritoneum and the cyst-wall.

Tapping the cyst with a large trocar, the fluid passed out through the canula, and was conducted by an india-rubber tube into a vessel underneath the table. About fifteen pints escaped in this way. An incision was now made into the tumor sufficiently large to allow the hand to pass into it in order to relieve the weight of the tumor. Cysts which had not been emptied before were now punctured, and the walls or septa were then broken down by the hand. The interior consisted of semi-solid masses, divided by trabeculæ into numerous cavities filled with a viscid, colloid substance. The diminished tumor was now drawn through the incision. As we found omental adhesions, which were quite extensive and bled upon the slightest touch, we tied the omentum beyond the adhesions, and divided between the ligature and the attachments. A portion of the omentum larger than the hand was removed, and the ligature brought out at the upper portion of the incision. All the ligatures and sutures used had been thoroughly carbolized, the material being Chinese silk.

The contents of the tumor having been broken down and the adhesions broken up, traction was now made, the edges of the wound being held by Dr. B. S. Woodworth so as to approximate the cyst and to prevent the escape of any portion of the intestinal canal, whilst I secured the pedicle by Atlee's clamp and separated the tumor with the knife.

The fluid and semi-fluid contents of the tumor

amounted to thirty-four pints. The cyst weighed six and a half pounds. Considering the specific gravity of the fluid in the third group of fluids usually or always belonging to multilocular cysts as from 1010 to 1040, the weight of the cyst with its contents was between forty and forty-five pounds.

The pedicle came from the right ovary; was seven inches in length, two and a half inches in width, and half an inch thick; it was easily managed, and there was no hemorrhage.

After the clamp was applied, it was so placed as to rest in the lower part of the wound. The opposite ovary was healthy, and the uterus normal.

The abdomen having been thoroughly cleansed, the wound was closed by silk ligatures about eighteen inches in length, threaded at each end on a strong straight needle. The needles were introduced from within outwards, through the peritoneum and the whole thickness of the abdominal wall, the ends of the sutures being held by an assistant, and a flat sponge placed over the bowels. All bleeding having ceased, the protecting sponge was removed, the sutures tied, and the ends of the threads cut off.

The part of the pedicle included in the clamp was mummified by the application of the persulphate of iron, and over it was placed charpie. Strips of adhesive plaster, the width of four fingers, were placed posteriorly and drawn over the front part of the abdomen, and made to fit snugly. Over these strips was placed cotton-wool, and over this was pinned a woollen binder, close-fitting. The patient was now placed in bed, with bottles of hot water to her feet and blankets about her, and morphia administered hypodermically. Threatening vomiting was prevented by pulverized ice internally and sinapisms over the epigastrium. No depression followed the operation.

Thursday, 4 P.M.—Pulse, 104; temperature, 97°; respiration, 32. During the next twenty-four hours the patient passed sixteen fluidounces of urine.

Friday, A.M.—Pulse, 108; temperature, 101°; respiration, 24. Twelve fluidounces of urine.

Saturday.—Pulse, 112; temperature, 103°; respiration, 24. Passed sixteen fluidounces of urine. Rested well; slept nearly the entire night.

Sunday.—Pulse, 100; temperature, 98°; respiration, 18. Slept well during the night. No thirst; continued the ice. Some symptoms of diarrhoea. At midnight, introduced a suppository of opium, and at 6 A.M., another. Surface moist. Free of pain. No flatulence. All this time she has subsisted upon a milk diet exclusively.

Monday.—Pulse, 100; temperature, 98½°. Rested well during the night. Continued milk diet. Opium suppositories continued. Slight abdominal pains from flatulence. Urine, sixteen fluidounces.

Tuesday.—Pulse, 100; temperature, 98½°; respiration, 18. Urine, eighteen fluidounces. Appetite good. Entirely free from pain; hopeful. Wound dressed by cutting the plaster and re-supplying it from the cut ends by attaching the new strips—dry dressing. The wound almost entirely healed; the pedicle dried up, will soon be removed; the slightest trace of pus only.

Wednesday (morning).—Pulse, 88; temperature, 97½°; respiration, 18. Slept during the night. 12 M.—Pulse, 84; temperature, 98½°; respiration, 19. Urine, sixteen ounces. Milk diet continued. Evening.—Pulse, 88; temperature, 99°; respiration, 16. No thirst. Appetite good. For the first time is lying upon her right side.

Thursday (morning).—Pulse, 88; temperature, 98½°; respiration, 18. Urine, sixteen ounces. Evening.—Pulse, 90; temperature, 100½°. 9½ P.M.—Free movement of the bowels without enema or purgative; relieved her of flatulence and pain. Slight abdominal

pain. 11 P.M.—I found her sleeping. Pulse, 80; temperature, 98½°; respiration, 18. Inclined to sleep. Directed the nurse to continue the suppositories of opium every six hours. She is now perspiring.

Friday, 6 A.M.—Slept well. One slight movement; costive, not liquid. No tympanitis. Pulse, 78; temperature, 98½°; respiration, 18. Appetite good. 9 A.M.—The stitches were removed, and the wound was found to have almost entirely united; pedicle dried up, and the clamp only a source of irritation; this we removed cautiously. After the application of powdered persulphate of iron, we applied dry charpie over the line of the incision, and the edges of the wound were supported by narrow strips of adhesive plaster. We now readjusted the broad strips of adhesive plaster, over them cotton-wool, and supported all by a flannel bandage. Appetite good. Beef-tea to-day, with bread. 6 P.M.—Pulse, 80; temperature, 97½°; respiration, 16.

Saturday, A.M.—Pulse, 80; temperature, 96°. Slept well during the night. Appetite good. 6 P.M.—Pulse, 84; temperature, 96½°. Very comfortable. Line of the incision united, nearly free from pus; pedicle united to abdominal walls. Nothing remains but the ligature applied to the omentum. One movement from the bowels; not liquid. No distention. Progressing finely towards a rapid recovery.

The omental ligature came away on the twenty-seventh day. The rebound to health was rapid and complete. This may be attributed partially to the preparatory treatment, and the complete isolation of the patient, with absolute rest.

NOTES ON THE PERFORMANCES OF TWO ONE-FIFTIETH OBJECTIVES.

BY JOSEPH G. RICHARDSON, M.D.,

Microscopist to the Pennsylvania Hospital.

IN selecting the subject of one-fiftieth objectives for my remarks this evening, I have been chiefly influenced by the fact that through the kindness of Dr. J. H. McQuillen, Corresponding Secretary, and Mr. Charles Stodder, a corresponding member of the Section, I have recently had the opportunity of examining a Tolles one-fiftieth immersion, and of comparing it with my own Powell and Leland's dry one-fiftieth, and also with my immersion one-twenty-fifth, made by Wales.

My experience with lenses of this focal length is too restricted to enable me to contribute much information regarding them, and my intention is therefore chiefly to elicit discussion, and to narrate the results of my own trials with the most scrupulous honesty, and, so far as lies in my power, without prejudice.

Among the test diatoms upon which I have brought these objectives to bear, the *Pleurosigma angulatum* offers, of course, no difficulties.

The transverse striæ of *Surirella gemma* are likewise easily shown by all these lenses, but the finer longitudinal lines are not distinctly visible by gaslight. Under the employment of monochromatic sunlight (Col. Woodward's ammonio-sulphate of copper method), these faint markings, which Frey says are "only to be mastered with much pains," are clearly visible even under the one-twenty-fifth. It is especially worthy of note that, in my experiments

a few days since, the basket-like arrangement of these lines, produced according to Hartnack by elongated hexagonal areolations, first came distinctly into view when the Wales immersion one-twenty-fifth was exchanged for the Tolles immersion one-fiftieth, and after I had vainly sought for it with the former. In this observation the obliquity of light, the kind of illumination, and my skill (or unskilfulness) as a microscopist were all constant factors, so that the superior performance seems certainly due to the superior qualities of the higher-power lens.

The transverse lines of *Amphipleura pellucida*, displayed by the aid of monochromatic sunlight, were better defined by the Tolles immersion one-fiftieth than by the Powell and Leland's dry one-fiftieth or by the Wales immersion one-twenty-fifth, the two latter only exhibiting the markings near the edges of the frustules.

Of the so-called Podura scales (of which we were informed at our last meeting it was "impossible to obtain slides with covers thin enough to be used"), I have now upon the table some good specimens of my own mounting, under cover about one-five-hundredth of an inch thick, which you will have an opportunity of "using" in testing the lens. As the result of my own comparative trials with central light, I find that the definition of the note-of-exclamation-marks afforded by the Tolles one-fiftieth is somewhat superior to that given by the Wales immersion one-twenty-fifth and the Powell and Leland dry one-fiftieth. Its advantage over the latter of these two objectives is very slight, being less marked than that shown when it is applied to some other test-objects. No one of the three lenses bears even the C eye-piece without marked loss of definition, greater in my opinion than that undergone by some of Mr. Tolles' or Mr. Beck's immersion one-tenths, even when combined with the E or No. 5 eye-piece.

Applied to my favorite test-objects, the salivary corpuscles, neither the Tolles, nor the Powell and Leland one-fiftieth, seem to surpass the working of Wales's one-twenty-fifth, either in exhibiting the dancing molecules, or in defining the delicate cell-wall which restricts the movements of the latter. Probably, however, long study and constant practice upon the globules of the saliva have enabled me to obtain proportionately better results in their resolution under my one-twenty-fifth, with which I have chiefly investigated their structure.

The statement of my friend Dr. Hunt that under this one-fiftieth a *Bacterium* looks like the mast of a ship in a fog, led me to careful examination of these organisms, and I am confident that his description applies chiefly to the object when seen just beyond the proper focus. The *Bacterium* so focussed seems, it is true, most sharply contrasted to the rest of the field; because, being cylindrical, it acts as an elongated convex lens, and concentrates the light in a line one-twenty-thousandth of an inch this side of its true position. Formerly I made the mistake of supposing that when this area of concentrated light was in focus, I had properly adjusted the instrument, and was much dissatisfied with the Wales

one-twenty-fifth because the outline of the object was indistinct. Prolonged study, however, taught me to perceive my blunder, and by correct focusing to bring into view the margins of the *Bacterium*, limited by a delicate hair-line almost as fine as can be drawn by an ordinary writing-pen; and this I have also done with the Tolles one-fiftieth now under consideration.

The fibrin filaments of coagulating blood, freshly drawn upon a slide, which in persons free from any inflammatory or cachectic tendency often form a test of moderate severity for the higher powers, are well shown under the Tolles one-fiftieth, and by its aid I observed that in one instance the net-work of filaments was confined to the lowest stratum of the drop, immediately in contact with the surface of the slide, and did not extend through the whole depth of the liquor sanguinis.

In order to overcome the insuperable obstacle which has hitherto prevented a one-fiftieth from being properly tested in Philadelphia, I have devised the following very simple method of mounting diatoms, Podura scales, etc., under "sufficiently thin covers." Select a piece of clear, colorless mica, and, having split it into layers about one-five-hundredth of an inch in thickness, cut it with sharp scissors into squares measuring one inch on a side. Then, with a writing-diamond or otherwise, cut or break the cover of a mounted slide of, for example, *amphipleura* (to the under surface of which the frustules adhere), into small fragments, say one-tenth of an inch across, and invert one of these upon a fresh slide, to which it should be attached by a minute portion of Damar varnish. Lastly, cover the diatoms, which remain adhering to what is now the upper surface of the fragment of thin glass, with one of your squares of mica, and seal up the latter at the edges with a very little Damar cement. Of course, thin sheets of glass, if they can be procured, may be used instead of mica, and are, I think, decidedly to be preferred, because less liable to become injured under careless manipulation, as well as permitting a somewhat sharper definition.

Finally, in regard to the other important but secondary qualifications of a good lens, I find that both these objectives are not quite achromatic; the Tolles glass being less perfectly corrected in this respect than that of Powell and Leland. Both lenses give a good flat field, and their magnifying power is fully up to the usual standard, as they each afford with the No. 1 or A eye-piece an amplification of over twenty-five hundred diameters.

I think it justly due to Mr. Joseph Zentmayer to add that several of the above-mentioned observations with the one-fiftieth objectives were made, with unexpected satisfaction, upon one of his new student's microscope stands. Although the stage movement in this form of apparatus is by hand only, and the fine adjustment beneath the stage is of a comparatively inexpensive variety, yet such are the delicacy and firmness of its workmanship that there was no difficulty, by careful manipulation, in obtaining excellent results as above stated, even with the highest powers.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, NOVEMBER 28, 1874.

EDITORIAL.

THE ASSERTED DECADENCE OF PHILADELPHIA AS A MEDICAL CENTRE.

A RECENT issue of the *New York Tribune* contains a long editorial upon New York as a medical centre, so untrue and unjust in its general drift, if not in many of its individual assertions, that we desire to say a few words in reply, especially as the *Philadelphia Medical Times* is quoted in the article. The gist of the column and a half is that New York has, as a medical centre, far out-distanced this city, which is stated to be proven by the facts that there are twice as many students attending the three New York as the two Philadelphia medical schools, that there are many more medical journals published in New York than in Philadelphia, and that the principal text-books of the country are written and published in New York.

Our comment upon these asserted facts is simply that they are not true. The *Medical Times* stated early in the winter, before the full classes were in town, that there were over six hundred medical students in this city: inquiry at the schools shows that the conjoint matriculant list now foots up to seven hundred and ninety. The assertion of the *Tribune* that there are nearly twelve hundred students in attendance on the three schools in New York City we believe to be a gross exaggeration. Our belief rests not merely upon general principles and the published reports of the New York colleges for last year, but also upon specific inquiry among those who are in a position to know. There appear

to be about eight hundred students in New York; certainly nine hundred is a very full, if not an excessive, estimate.

The *Tribune* enumerates twelve medical journals as published in New York. Several of them are, strictly speaking, not medical journals; one, at least, not a journal at all. On making out a parallel list for this city, we find that it reaches to the number of ten. Of the New York journals, three or four are still in the year of their birth, and the infant-mortality in our neighbor city is as excessive among journalistic enterprises as among human beings.

If the number of issues printed per year is taken as the basis of comparison, and not merely the number of journalistic titles, Philadelphia is ahead of New York. The latter city gives to the world yearly eighty-seven numbers of medical journals, whilst Philadelphia issues one hundred and sixty numbers. It would be very difficult to get at the official figures, but we believe we are correct in stating that more individuals are reached by the Philadelphia than by the New York medical press.

Taking up the question of text-books: of the seven branches usually taught in the colleges, Philadelphia holds almost undisputed sway over one, and in several is contested only by foreign treatises, whilst New York does not hold the market in a single instance. In *materia medica and therapeutics*, American books written and published in Philadelphia absolutely command the market. In *surgery*, the greatest work extant in the language is that of Prof. Gross of this city; whilst Ashhurst's and the reprint of Erichsen supply almost wholly the demand for less comprehensive treatises. New York contests, it is true, for a share by means of the recent book of Dr. Hamilton. In *obstetrics*, Hodge's great treatise is the only American work of any authority at present on the market. In *physiology*, New York is undoubtedly pre-eminent; but we are sorry to say that Philadelphia reprints of English works largely interfere with the sale of the very meritorious treatises of Draper, Flint, and Dalton. In *anatomy*, the only American work of present authority is the product of a Philadelphia pen. In the *practice of medicine*, both New York and Philadelphia are represented, with, so far as we know, equal sales. In *medical chemistry and toxicology*, Philadelphia has produced several recent standard treatises; New York not any. Indeed, if medical activity is to be measured by the production of successful text-books, our ambitious neighbor is, in racing parlance, "nowhere."

New York is, however, decidedly ahead of this

city in the cultivation as well as in the literature of specialties: this we freely acknowledge; and it seems to us the only danger, so far as New York is concerned, of our city's losing its medical pre-eminence. The causes that have led to this are, we hope, however, dying out. As our allotted space is full, we must reserve their consideration for a future occasion.

WE print to-day an article from the pen of Dr. Garretson as a leader, partly in order to give prominence to it, and partly because in many points we agree with the sentiments therein expressed. As comment, we simply reiterate what we have before said, that if dentists are ambitious to be considered medical specialists they must undergo a general medical education; that so long as there are distinct dental colleges giving a peculiar degree, so long will physicians refuse to acknowledge dentists as members of the profession. An individual dentist who has taken the medical degree may assuredly be received as a brother practitioner, but a simple D.D.S. never. The difficulty with the physician practising dentistry is that he is classed by the general and medical public with the mere dentist. Why should there be D.D.S., any more than D.O.S., or D.A.S., or D.T.S., or D.S.M., etc., etc., *ad nauseam*?

LEADING ARTICLES.

UNIVERSALITY IN EDUCATION—SPECIALISM IN PRACTICE.

THE heading of this article, which constitutes a curt putting of a most important matter by a former editor of this journal, serves particularly well as a text to a few thoughts which the writer wishes to present concerning the specialty of Oral Surgery.

It is a fact not to be denied or disputed, that, as communities grow in numbers and in intelligence, so the work of the individual members thereof breaks itself up into the practice of specialties; and this occurs as the result of an organization in man which leads him to take cognizance of results as evidences are presented to him in the practical working of things.

Specialism, however, is a bad thing for the individual man; that is, it is bad for him whose manhood and whose mental powers are merged and allowed to become lost in specialism; it is, on the contrary, a great good thing for a community at large, as is demonstrated by the voice of that common experience out of which the practice obtains and grows.

The bad of specialism finds all the antidote possible in that circularity of education which is the constant reminder to a specialist of the littleness of the work

in which he is engaged: it holds him to modesty and to a becoming humility in the presence of the *alma mater*; it is the balance-wheel.

That the profession at large have long been found disposed to ignore specialties and the specialists is a matter not at all to be wondered at, neither found fault with. Specialists, until the present age, have almost universally proved to be arrant quacks; and the assumption by such of a pretension to belong to the grandest of professions could not possibly have proved else than a stench in the nostrils of the educated and refined. The title of doctor ought to imply a very great deal; and to him whose learning and whose habits of thinking and acting place him on a level with the proper meaning of such a title, it cannot but appear as an offence in any one whose assumed relation with the degree serves but to degrade and to belittle it.

As a specialty, what is known as Dental Surgery has assumed prominent place, and it has come to such position because of the intrinsic merit found in it. It embraces a multitude of doctors,—this term being employed in the fulness of its ordinary meaning,—and it affords harbor for perhaps quite its share of impostors, whose knavery is equalled only by their ignorance and impudence. In the ranks of this specialty, the writer does not hesitate to say, are to be found some of the best-educated men in the country; and, so far as the ethics are concerned, he has as little hesitation in affirming that he has never met with higher sense of honor among practitioners of any profession: the physician at large may claim no precedence over the dentist in this respect.

Like general surgery, the dental specialty has had an up-hill track; and, like surgery at large, it has come to its present position because of the good encompassed in it, and which good the people cannot do without. As a specialty, it is a something fixed; it is a thing that is.

Has it attained to its highest good?

Galen, centuries ago, made the assertion "that the cause of the toothache was known alone to God." In this remark resides, perhaps, the origin of dental inquiry. Compare now this ignorance with the experience comprised in the dental curriculum of to-day. Such a comparison will best show what dentists and dentistry have done.

But what has been accomplished, while it is very much, is seen and felt by the true leaders of this specialty not to be any way near what is to constitute the fulness of its work; hence, year by year, the studies pursued in dental colleges grow wider and wider. Chairs of surgery have been established; chemistry is taught with a thoroughness that leaves little to be accomplished; physiology, not satisfied with the textbooks, takes its secrets from organs which pulsate and are alive; diagnosis has long ago passed beyond the mystery of Galen, and seeks to-day for the hidden things which lie among brain-cells and hepatic lobes. To-day, to be a professor in a dental college is to occupy a position that reflects honor on a man, and which

affords the occupant of such a chair a field of great usefulness in which to labor.

Dental surgery, however, is but a little part of a common circle to which its duties pertain; hence, step by step, slowly, it is true, yet surely, is the specialist of this department advancing to a work more worthy his education, and more in correspondence with the claims he puts forth to belong to a learned profession; the dental surgeon is advancing into the oral surgeon.

Oral surgery—while it educates the dentist, simply as a dentist, more soundly and scientifically than heretofore—treats of the diseases and surgery of the mouth, jaws, and associate parts. What it is, the writer cannot but think that he has clearly and explicitly set forth in his book, entitled "A System of Oral Surgery," and he may not but rest under the conviction that many years will not elapse before it will be found that in this new departure the complexities of the surgery of these parts will be rendered not less plain than have been the mysteries of Galen's confusion concerning the cause of toothache. In such a new departure, suffering humanity will come to a gain of not less consequence than that found in the establishment of the specialty of ophthalmic surgery; and who does not understand what great good has been evolved here?

But to be an oral surgeon demands in every respect the same order of education that pertains to the surgeon and physician at large. Hence, all practitioners of dentistry who have advanced into this new field are found possessed of the degrees both of dental and medical colleges; and, as things now exist, these two roads must be passed over before one can come to any ability to practise oral surgery: he must pass through a dental school that he may perfect himself in the knowledge of dental surgery; he must go through the medical college that he may know of general practice. And even yet a deficiency is found. The means to make special study of his special subject the medical school fails properly to furnish. He may listen to a few lectures on the subject of mouth- and face-operations, and the clinic will furnish him distant views of mouth-diseases, but these are not at all sufficient to his purpose. He needs to handle, to operate, and to prescribe for himself.

The oral surgeon needs lessons which, as yet, are widely scattered,—so scattered, indeed, that to attempt to master the subject, as becomes a specialist, is necessarily to involve one's self in expenses which the purse of few students will be found able to bear.

What, now, is the remedy?

No question is so constantly propounded to the writer as the query concerning the manner of studying oral surgery; and it is a confession he is compelled to make that there is no plain answer to it.

The medical college, as at present constituted, cannot make an oral surgeon, neither can the dental school. The one teaches well and fully part of what the student desires to learn, and the other informs him as thoroughly in another direction of the knowledge required; but these are as two end-spans of a bridge

the middle arch of which is lacking,—a bridge all right so far as it goes, but over which one cannot pass.

The question is seen, therefore, to resolve itself into one of a new departure,—a departure felt to reside in that same evolution which brought the specialty into being. Should dental schools resolve themselves into full medical colleges? or will it be that the demand shall be met by the establishment of special hospital advantages in connection with the already matured medical institutions?

To one intimately acquainted with the classes of professors connected with the two orders of schools, these queries are not so easy of answer as they would seem to be to him who knows alone either side. Dental colleges are as young men overflowing with the vigor of fresh life. It is a mistake to think these incompetent to the task; it is only that they delay on the Cisalpine side of the Rubicon; once in, they will hardly stop short of Rome. Medical schools, on the contrary, hesitate because they doubt the humor and intentions of the men they would gladly receive into the order of their alumni: they do not fully recognize the stature to which the confrère has developed.

A specialist cannot, and should not, be received into the common brotherhood of medicine without his coming to a common platform as regards all that makes the doctor. The ophthalmic surgeon has recognized this; and to-day he occupies just such a position as it is desirable to enjoy,—he has his special hospitals, but he has no college, no peculiar diploma. His general education is alike with his medical brethren; his privileges are the same.

The writer may here stop. Further than presenting these brief data, he does not feel at liberty to intrude on the pages of this journal. He has desired simply to suggest the consideration of the subject to those who are intending to become oral surgeons, and, as well, to those who are to decide the questions as to how oral surgeons are to be educated. Shall such decision be rendered first by a medical or by a dental school? Will the ranks of oral surgery be filled by those who are to-day physicians, or will the matriculants come from among those who now are at the head of the dental specialty? Come from somewhere they surely must, and will: evolution, like revolution, never goes backwards.

JAS. E. GARRETSON, M.D.

PROCEEDINGS OF SOCIETIES.

AMERICAN PUBLIC HEALTH ASSOCIATION—THIRD ANNUAL MEETING.

SECOND DAY—MORNING SESSION.

THE proceedings were opened by the reading of a paper by Dr. Ezra M. Hunt "*Upon Building-Ground in its Relations to Health and Disease.*"

After going over the various causes of insalubrity dependent upon covering of the surface of the ground by buildings, resulting in increase of ground-water,

defective aeration of sub-structures, etc., the author recommended more perfect systems of drainage as distinct from sewage systems in our city.

At the conclusion of the paper, Dr. Ray, of this city, remarked upon the exceedingly flimsy construction of sewers and drains in Philadelphia. Made of but one thickness of brick, and that porous, and cemented together by mortar containing a large proportion of sand, it was a natural result that the sewage should soak through and permeate the ground in every direction. So wretched, indeed, was often the construction of these sewers, that he had known instances where they had actually fallen in before the workmen had left the ground.

Further remarks upon the subject of drainage and disposal of sewage were made by Drs. Bell and Morris, of New York, and Mr. Warner, of New Haven.

Dr. Stewart, of the Board of Health of Baltimore, gave a sketch of the present condition of affairs in that city as regards the disposal of sewage. Baltimore, Dr. Stewart remarked, is honeycombed with privies; the sanitary arrangements are not good. Many privy-wells are dug forty feet deep in the cellars of the various houses, and are not intended to be cleansed, and the fecal matter is disseminated through the soil, and becomes a fruitful source of typhoid fever.

Mr. Winans has arranged a system of air-tight tanks to be used in certain model tenement-houses which he has built. These are removed, when filled, to some locality outside of the city limits, and then emptied. In Washington, old oil-tanks are used in a similar manner. It is proposed to build a complete system of sewers for Baltimore, the expense to be met by the issue of sewer-bonds; each householder to pay for the privilege of tapping the street-main, as is now done as regards the water-supply.

Dr. Hartshorne followed with some remarks on the unhealthfulness of watering-places, which, owing to defective sanitary arrangements, often become the causes of death to the invalids seeking them.

Dr. S. C. Busey, of Washington, then read a "*Report upon the Gathering, Packing, and Transportation of Fresh Vegetables and Fruits, Competent Inspection, and Free Markets for Producers.*"

The Association then proceeded to the election of members and the transaction of routine business.

AFTERNOON SESSION.

Dr. E. Harris, of New York, presented a "*Report upon the Sanitary Government, Vital Statistics, and Methods of Public Health Administration in the Cities and Large Towns of North America.*"

This report, he remarked, was so occupied by detailed statistics that he would not weary the Association by reading it, but would suggest that it should be referred, as the other papers had been, to the executive committee.

Dr. J. M. Toner, of Washington, D.C., then read a paper entitled "*Notes on some Conditions and Accidents which Endanger, Limit, or Prevent Vaccination from giving Full Protection against Smallpox.*"

Dr. Toner remarked that what he had to say would be of a very practical character, and might seem trite, particularly to those physicians who had devoted themselves to the study of public health. Nevertheless, the fact of the revival of smallpox from time to time in an almost epidemic form is a sufficient cause to claim attention, especially when it occurs, as it does occasionally, in those who had supposed themselves to be protected by vaccination.

Some of the conditions which prevent people from gaining almost complete exemption from smallpox are wholly public in their character, and exist outside of and beyond the control of the physician in civil prac-

tice. These are, want of proper appreciation by numbers of people of the safety, utility, and sufficiency of vaccination, and of their own danger; the negligence of some who appreciate the value of the practice, and the utter recklessness of others.

The remedy of most of the evil that rests with the public must be sought through a judicious system of universal vaccination and re-vaccination enforced by law, under a skilful physician employed for the purpose.

There are also defects in the practice of vaccination as at present conducted, but they are of a character to be remedied, corrected, or prevented. Some of these depend upon the condition, age, and habits of the patient; others grow out of the care taken by or of the individual after the virus is introduced; and still others relate to the genuineness of the virus itself, its freshness, its proper introduction, and its security against interference through every stage of its development and decline.

Dr. Toner went on to speak of the various accidents which might interfere with the operation of vaccination and its results, and urged strongly the necessity of practical and special training for public vaccinators. It is of the highest importance that the virus should be fresh and perfectly pure. Of course, nothing could be better than the virus from the animal itself; but the speaker thought that conclusive proof is wanting of the deterioration either in the activity or protective quality of the humanized vaccine lymph, when selected with care, introduced with judgment, and properly guarded from accident.

He then detailed the method of vaccination which he believed the most effectual, advocating especially the use of a sufficient quantity of lymph or crust, and its introduction at two separate points. Failure to induce vaccination was, he remarked, more frequently because of the virus used, or want of skill in the operator, than of insusceptibility of the individual. In the United States the difficulty lies more probably in the insufficient quantity of virus used, rather than in its defective quality. Carelessness on the part of the vaccinators, and the almost exclusive use of the crusts instead of lymph, may also be cited as among the leading factors in the cause of failure.

Dr. Toner does not believe there is any danger of communicating other diseases with the vaccine disease. Marsden, who has vaccinated over fifty thousand individuals, has never observed an instance. Spurious vaccination may occur when the best lymph is used, and may vitiate the results of the operation. Dr. Toner concluded his paper with some practical directions as to the proper method of vaccination.

Dr. Moreau Morris said that several points had occurred to him while Dr. Toner was reading his paper, which he had jotted down, and would read. First, in regard to the frequent failures of vaccination. He had had a good deal of experience in the operation, and believed the cause of failure usually to lie in the imperfection of the virus, or in an improper method of operating. It is not unusual for a practitioner who wishes to vaccinate a patient, to ask his nearest neighbor for some virus. An old crust is produced, or a quill or two which has been kept for an indefinite period, and this is used.

Having had charge of the public vaccination during the late smallpox epidemic in New York, Dr. Morris was surprised at the amount of ignorance and carelessness manifested by many who performed the operation. Some would take an ordinary lancet and make several scarifications from one-eighth to one-ninth of an inch deep, causing considerable bleeding. Then a quill would be rubbed over the surface, and that would be called "vaccination." Of course, under these circumstances, it would rarely "take." Others would

scarify the surface superficially,—an equally useless proceeding. To show the perfectly protective character of proper vaccination, he might mention his own experience in New York, where, in two hundred thousand cases of vaccination of which a record was kept, no cases of smallpox occurred subsequently.

As to the use of humanized or bovine lymph, he was satisfied that the former was equally efficacious with the latter. The lymph, however, must be fresh, and kept at a proper temperature to avoid decomposition.

As regards the number of points at which the virus should be introduced, Dr. Morris agreed with Dr. Toner in thinking that it should be done in several distinct localities for security, though a single good inoculation is sufficient. One point Dr. Toner had not brought out,—the necessity that the system should be saturated with the virus.

Dr. Morris, as a rule, repeated the vaccination on the eighth day; often, when the first vaccination has seemed successful, the re-vaccination has run its course. He mentioned in this connection the case of a person who was peculiarly exposed, and who was vaccinated successfully three successive times. Among the causes of the non-success of vaccination he had found the use of dirty lancets and imperfect inspection by the physician, who too often is satisfied with the statement of the patient or friends that it "took."

Constant inspection on the part of the physician is alone satisfactory. As to the material used, good crusts would answer, but he would prefer lymph. In conclusion, Dr. Morris said that a course on vaccination should be a part of the education of every medical student. Vaccination is an art, and cannot be picked up.

Dr. Edwin M. Snow, of Providence, Rhode Island, then read a paper upon the question, "*Does Smallpox become Epidemic, or is it spread solely by its own Contagious Property?*" Dr. Snow said that the phrase "epidemic smallpox" is common in writings upon medical and sanitary subjects. Whenever that disease is prevalent in any place it is freely and generally spoken of as "epidemic," without, apparently, any very definite idea of what is meant by the word.

We have all seen times when the smallpox seemed to spread more rapidly and more easily than at other times, and when vaccination seemed to "take" more readily. But does this condition of things, when it exists, depend upon any epidemic influence of the smallpox-poison? In other words, can smallpox become epidemic? Dr. Snow thought not. Taking as a basis the Fourth Annual Report of the Massachusetts State Board of Health for the year 1872, we find that although it is there stated that a wide-spread epidemic influence of smallpox-poison prevailed, yet, in fact, there was no marked prevalence of the disease at that time in this country, except in Boston and in a few Western cities. As this is simply a question of fact, he might quote a few figures. In the thirteen months including 1872 and the first part of 1873, notwithstanding this so-called epidemic influence of smallpox, there were of 342 towns in Massachusetts 145 where not a single case of the disease, modified or unmodified, occurred. In only 86 towns of 342 were there more than five cases of smallpox or varioloid during that time. Certainly we cannot be expected to believe that an epidemic of smallpox such as the report so vividly describes existed in any town that had less than five cases of smallpox or varioloid in thirteen months.

After giving further statistics, obtained from this report, to the same effect, Dr. Snow continued as follows: Was this, then, an epidemic influence, or can it be explained more rationally in some other way? We understand by an epidemic influence some cause of disease which is wide-spread in its effects upon the

people, which is independent of the ordinary or sporadic causes of disease, and which in itself and by itself has some power towards producing disease. Thus, for an illustration, when Asiatic cholera is truly epidemic there is wide-spread over the country an influence which of itself tends to produce cholera, and which, in connection with local causes, does produce it, and without which the cholera cannot exist, even though all the local causes may be present. Can we conceive of any such influence in connection with smallpox? any influence that can be correctly called epidemic? We all acknowledge smallpox to be contagious, and, so far as we know, no case of the disease ever occurs at the present day without contagion, either direct or indirect. There may be causes, like cold, which preserve the contagious virus and make it more active; and there may be causes, like heat, which tend to weaken and destroy its power; but we can conceive of no cause that will have the slightest tendency to produce a case of smallpox without contagion.

Let us consider for a moment what a case of smallpox is. Each case, from its beginning to its close, is a living manufactory, in active operation, of virulent contagious poison. Every part of the body, yes, every pore of the body, exhales this poison; every secretion of the body is saturated with it. It is manufactured in the skin at first in a liquid form, and then dries up, and is preserved in quantities sufficient in each ordinary case of smallpox to give the disease to millions of persons. All the clothing, bedding, and furniture of the sick-chamber are infected with the poison, and give it forth into the atmosphere every time they are moved. More than this, every person sick with smallpox is breathing forth volumes of the contagion with every respiration. Thus the six hundred thousand cubic inches of atmospheric air that each patient inhales each day come forth from his lungs changed into a virulent contagious poison.

It seems to me that the interests of sanitary science require us to repudiate the idea that the prevalence of smallpox may depend upon any mysterious influence called epidemic. The language itself is inconsistent and absurd. Smallpox is the result of a specific poison applied to the human body through the skin or through the lungs, and producing definite specific effects. The vaccination-disease is the result of a specific poison applied to the human body through the skin, and producing definite specific effects. Both the vaccine disease and smallpox are frequently prevalent in our cities to a greater or less extent; the vaccine disease much more so than the smallpox. May we not as well speak of the epidemic influence of the vaccine poison as of the epidemic influence of the smallpox-poison? We do not need the theory of "epidemic influence" to account for the prevalence of smallpox in any place; nor can we agree that such a theory is any valid excuse for such a prevalence of the disease. In this assembly, certainly, the doctrine is established that smallpox is propagated by contagion, and that we have in vaccination an almost absolutely perfect preventive of it. Whatever, then, may be our views in regard to epidemic influence, as sanitarians we must all agree, with reference to any and to all cities and communities, that the prevalence or the absence of smallpox will always be in exact ratio to the neglect or the observance of sanitary measures, including vaccination, by the authorities and by the people.

Dr. Hartshorne agreed with Dr. Snow in most of his views: there seemed, however, occasionally to exist an atmospheric saturation, or a rapid multiplication of morbid matter. A certain periodicity or alternation from generation to generation of susceptibility has been suggested, and seems possible.

Dr. Snow asked if it were likely this number of cases could exist if they had been vaccinated.

Dr. Hartshorne said he thought the average amount of vaccination from year to year was about the same.

Dr. Woodward differed from Dr. Hartshorne, and thought that while vaccination might be largely practised during and immediately subsequent to the general prevalence of the disease, yet a few years afterwards it would be performed to a much less extent.

Dr. Morris remarked, in answer to a suggestion of Dr. Hartshorne that some unvaccinated escaped, that these were probably not exposed.

Dr. Hartshorne disclaimed any intention of making light of vaccination.

Dr. Morris said that the idea of epidemic smallpox was as absurd as that of epidemic vaccinia. A small-pox-hospital under his care during the late prevalence of the disease in New York gained the credit—though isolated and in a suburb—of spreading the affection in the neighborhood. On close investigation, however, it was found that a person was in the habit of buying the clothes of those who died, which garments being cut up into rags were made into carpets in the village, and thus acted as carriers of the contagion.

A conference upon the subject of *Hospital Construction and Management* was then announced. Dr. Kirkbride, being called upon to open the discussion, said that he had come rather to receive than to impart information on the subject.

He had supposed that the questions of the construction of hospitals and of heating and ventilation were settled. We are now told that temporary hospitals are the best. His opinion, however, was different, and he believed that permanent hospital-buildings offered the best advantages.

Dr. Kirkbride then went on to speak of what he believed the proper mode of construction. After speaking of the importance of a good cellar, etc., he said that he thought the question of ventilation ought to have been settled by this time. Heat was necessary; no ventilation is perfect without the use of a fan. At that season of the year when ventilation was most needed windows were of no use. Forced ventilation is as necessary in summer as in winter. This method had been in use for a long time in the institution with which he was connected, and they were so well satisfied with it, that should they erect new buildings they should be arranged in the same manner. The best-managed hospital, he concluded, is always the cheapest.

Dr. I. M. Woodworth, Supervising Surgeon U. S. Marine Hospital Service, read an abstract of his last report "*On Hospitals and Hospital Construction.*" The hospitals built by him had been on the barrack plan. A hospital should be well situated, simple in construction, and one story high. The administration buildings alone should be permanent. The pavilions should be placed north and south, and at a distance apart equal to double their height. Though one story permits better ventilation, yet two-story buildings are allowable. Each patient should be allowed eighteen hundred cubic feet of space. Bath-rooms and water-closets should be entirely separate from the wards, and the latter should be ventilated by a large pipe running to the top of the building. The ward floors should be made of compact wood, the joints being filled in with white lead, and paraffine oil or beeswax should be used over the surface.

Washing the floor while patients are in the ward should not be permitted. The wall should be covered with lime-and-sand plaster, well painted, and frequently washed with soap and water; or it should be white-washed, and scraped at short intervals. Open grates should be employed, whatever other means of ventilation be used. All drains should be well ventilated by pipes passing to the top of the building.

One executive head, well paid, should direct the whole management.

Dr. Ray said his experience went back over a period of thirty-five years. It used to be considered that doors and windows allowed sufficient ventilation. That idea gradually became superseded by the more enlightened opinions of the present day. Forced ventilation was, in his opinion, what is required.

He regretted to hear Dr. Woodworth recommend oiled floors. Oil absorbs dirt, and his experience was adverse to the use of floors such as Dr. Woodworth had spoken about. He thought that washing a floor thoroughly once in two weeks would keep it clean.

Dr. Woodworth explained that he meant boiled linseed oil, which afforded a hard surface.

Dr. Ray in reply said that oiled floors would not shed dirt; all that he had ever seen had been always dull and dirty.

Dr. Ashhurst agreed with Dr. Kirkbride in regarding the objections to permanent hospitals as unfounded. Although from experience he could speak favorably of pavilion wards in military practice, yet in civil hospitals they had the disadvantage of being difficult to administer and requiring more attendants than could be afforded.

As regards the statistics of hospitalism, nothing was more difficult than to compare two institutions together which were not only in different localities and differently managed, but where different operations might be performed for the same injury. The character of the patients, too, would have to be taken into account. In army hospitals during the war, for instance, the men were generally healthy and supported by the morale of continued victory. It would be obviously unfair to compare the statistics of these hospitals with those of municipal hospitals filled with the dregs of the population.

Our hospitals are not perfect, but they are far from being the slaughter-houses some have represented them to be. No surgeon would willingly treat severe injuries in the homes of our poorer population, and the choice must lie between these and the hospital. Dr. Ashhurst was glad to see such unanimity of ideas as regards the essentials of hospital construction. One-story hospitals are theoretically better, but they take up too much room.

Dr. Woodworth, he was glad to observe, admitted that two-story hospitals were proper. Our city hospitals usually have three stories, but the upper one is generally held in reserve. As to the question of permanent or temporary hospitals, he believed the permanent plan the best.

Dr. Billings agreed with Dr. Ashhurst that the differences of opinion on this question were more apparent than real. What is wanted is sufficient dilution of the effete air. In old times eight hundred cubic feet used to be allowed to every patient in a hospital, but now the allowance has risen to twenty-five hundred feet, and some even recommend thirty-five hundred feet per hour; though, indeed, others think that three hundred feet per hour is enough. A municipal hospital should have a resident medical superintendent. The staff will not take care of hygienic matters.

Dr. Harvey Brown's "*Report upon Yellow Fever on the Dry Tortugas*" was referred to the executive committee, as was also Dr. Rodenstein's "*Notes upon the Causation of Scarlatina, etc.*"

Dr. Benjamin C. Miller then read a "*Report upon the Methods of Treatment of Gases from Rendering-Tanks, and the Disposal of Tank Offal.*"

At the evening session discourses were delivered by General E. L. Viele, of New York, on "*Principles and Practice in Drainage and Sewerage in Connection with Water-Supplies*," followed by a discourse by Prof. Edward Orton, of Ohio, entitled "*Certain Relations of Geology to the Water-Supplies of the Country.*"

THIRD DAY—MORNING SESSION.

After disposing of a certain amount of business, election of officers, etc., Dr. Stephen Smith, the President of the Association, read a paper "*Upon the Reciprocal Relations of the Public Health Service, and the Highest Educational Qualifications of the Medical Profession.*" After giving a general sketch of the condition and status of the medical profession at different periods of the world's history, the speaker referred to the present position of the profession in this country, where, according to law, "*the term physician may be applied to any one who publicly announces himself to be a practitioner of this art, and undertakes to treat the sick either for or without reward.*"

To the Public Health Service we must look for the first advance in the future, and when the needed reforms in medicine are effected it will take its proper rank in society and in the state. Purified, elevated, it will again be regarded, in its power to prevent and cure disease, as a divine art.

Dr. Sturgis, of New York, then read a paper entitled "*How does Syphilis affect the Public Health?*" He had divided the subject into three heads:

1. Is syphilis of common occurrence?
2. Can it be considered a disease fatal to life?
3. Does it favor the development or fatally influence the course of other diseases?

The statistics examined embraced only cases of syphilis properly so called, and did not include gonorrhœa or "chancroid." The facts were obtained from the reports of the Armies and Navies of Great Britain and the United States, the reports of the mercantile marine of the latter, the sum total of poor patients treated during the year 1873 at the various hospitals and dispensaries of New York City, etc.

In the U. S. Army, the statistics of mean strength from 1840 to 1859 show a percentage of 1.1 cases of syphilis. For the five years from 1870 to September, 1874, inclusive, the percentage of syphilis in the Department of the East was 4.61.

The report of the mercantile marine for the United States for 1872 and 1873 gives 15.33 per cent. as the proportion of syphilitic to other diseases.

The report of the mercantile marine of New York City from January, 1871, to October, 1874, gives the percentage of syphilitic to other cases treated as 16.19.

Reports of the British Army for 1869, 1870, and 1871 show the percentage of syphilitic cases as 7.6 of the entire force.

The statistics of the Naval Hospital of Brooklyn for the years 1870 to 1874 show that 8.59 per cent. of all cases treated were syphilitic.

The percentage of syphilis among the poor of New York, as shown by reports of hospitals and dispensaries, is 1.5 per cent. of all cases treated. The defective registration of patients is so prevalent that this figure is probably too low.

The English reports of Mr. Wagstaffe show that in London nearly seven per cent. of all the poor who receive medical relief are affected by syphilis.

The figures of M. Lecour show that in Paris the condition of affairs is about the same; and these statistics, as a whole, indefinite and variable as they are, are presented with a view of showing that the disease is probably widely spread.

In regard to the second question, whether syphilis can be regarded as the cause of a large number of deaths, Dr. Sturgis thought it could not.

Statistics were collected from the leading London hospitals, from the Charity Hospital, New York, and from various other sources, and with a result likely to prove surprising to those who regard acquired syphilis as a fatal disease. At St. Bartholomew's, during the

twelve years from 1860 to 1871 inclusive, one per cent. of all the syphilitic cases treated died.

At St. Thomas's, for six years (1866 to 1871 inclusive), four per cent. of all syphilitic cases under treatment died.

At St. George's, for five years (1866 to 1870 inclusive), 1.5 per cent. terminated fatally. At the London, during three years a little over three per cent. died. At the Charity Hospital, Blackwell's Island, during four years a little over .3 of one per cent. died.

These figures comprise only the secondary and tertiary forms; primary and congenital syphilis are not included. The immediate causes of death were ascertained in sixteen of these cases, and it would be difficult to ascribe them all to syphilis, except indirectly. It should be noted that in all the cases of death the end was accelerated, if not caused, by diseases which are in themselves serious, perhaps actually fatal, apart from any consideration of syphilis. Turning to the mortuary record of cities, we find in London in 1871 the percentage of deaths from syphilis to the total number, .8. In New York, for 1871, percentage of deaths from syphilis to total number, 1. Philadelphia, 1871, percentage of deaths from syphilis to total number, .2.

In face of these figures, would it be fair to consider syphilis as a fatal disease? Decidedly not.

As regards congenital syphilis, the case is different.

In London (1871), the percentage of deaths under five years to the total deaths from syphilis was over eighty-nine; in New York, over eighty-four; in Philadelphia, over sixty-three: truly, a wholesale massacre of the innocents. Large as these figures seem, they are borne out by the statistics of other countries. During recent years, the percentage of mortality from syphilis has apparently increased, probably on account of more accurate registration.

The effects of syphilis are serious enough; but Dr. Sturgis most earnestly protested against exaggerating them. The danger to the public health from syphilis lies not so much to those who acquire the disease as to those who inherit it.

As to the third question,—Does syphilis favor the development, or does it fatally influence the course, of other diseases?—Dr. Sturgis brought forward much carefully-prepared statistical matter, as well as details of cases coming under his own observation.

In summing up his communication, Dr. Sturgis stated the following conclusions:

1. Syphilis is probably widely spread, possibly increasing in extent. This opinion, from the imperfect means at our disposal, must, for the present at least, remain more or less as conjecture.

2. The question of the fatality, so far as the acquired forms of the disease go, may be answered in the negative; but its excessive mortality in the congenital variety renders it serious and alarming. One cause of consolation remains, however,—*i.e.*, that the disease does not probably extend to the third or fourth generation, usually dying out with the second; nor does it transmit any specially vitiated vitality to the posterity of the original sufferer.

3. In the third proposition the same condition is found, *viz.*, the comparative harmlessness of acquired and the fatality of congenital syphilis over the course and development of other diseases.

The danger to the public health lies more in the transmitted than in the acquired disease, and whether it be permanent and dangerous or only temporary and remediable must remain for future investigation to show.

Dr. Sturgis closed his admirable paper by a suggestion for the better registration of this kind of cases and for more trustworthy observation, quoting the recommendations of the International Statistical Congress held at St. Petersburg in 1872, at length.

Dr. Sturgis's paper was succeeded by the following :

A paper upon "*Hay Fever or Summer Catarrh*." Original Researches upon the Geographical, Topographical, and other Etiological Characteristics of this Malady, with reference to its Causation and Prevention. By George M. Beard, M.D., New York.

A paper upon the "*Influence of the High Altitudes and Climate of the Table-land Country of the Rocky Mountain Region upon Health and Disease*." By B. E. Fryer, M.D., Surgeon U.S.A.

"*Abstract of Special Reports by Army Medical Officers on the Effect of Mountain Climates upon Health*." Presented by J. S. Billings, M.D., Assistant-Surgeon U.S.A.

"*Certain Perils of the School-Room which demand the Attention of Educational and Sanitary Authorities*." By A. N. Bell, M.D., Brooklyn, New York.

A paper upon the "*Stealthy Introduction and Spread of Infectious Diseases in Large Cities*." By John C. Peters, M.D., New York.

A paper upon "*Suicide in Large Cities with Reference to certain Sanitary Conditions which tend to prevent its Moral and Physical Causes*." By Allan McLane Hamilton, M.D., New York.

After the reading of these papers a sanitary conference was held, at which the comparative merits of water-closets and privy-vaults were discussed, after which the Association adjourned to the evening session, which was held at Horticultural Hall.

At this session discourses were delivered by Hon. Dorman B. Eaton, of Washington, on "*Health Laws and the Interests and Obligations of the State and National Governments pertaining to them*;" and by Hon. L. H. Steiner, M.D., of Maryland, on "*Health a Prerequisite of National Success in Peace and in War*."

Short addresses were also made by Rev. Dr. Beadle and Dr. Agnew. On motion of Dr. Gross, the thanks of the Association were tendered to the gentlemen who had delivered discourses, and the Association adjourned.

The meetings of the Association were, on account of pressure of business, prolonged over Friday morning, at which time Prof. Maisch's paper upon "*Sanitary Relations of Pharmacy and the Materia Medica*" was read.

Prof. Maisch, after speaking of the importance of pharmacy to the general welfare, and of the vast amount of adulterated drugs formerly supplied to the American market and still supplied to a considerable extent, went on to allude to the various "formulæ" and special preparations now so much in vogue, and which are often inert or harmful.

In the way of remedy for these acknowledged evils, he suggested that the medical profession recognize the want of household remedies by publishing authoritative formulæ for the use of pharmacists, who may compound them at their counters and keep them on hand for the ready and convenient supply of all the real wants of families and of individuals in this direction. Such a measure would go far towards abolishing a large number of nostrums; but it would be advisable not to neglect the direct instruction of the public, by publishing tracts on sanitary subjects, by the delivery of popular lectures, and by instructing the rising generation in the means of preserving the health and in the dangers of the injudicious use of all drugs.

An aid to this would be an almanac gotten up by some competent authorities under the auspices of an enterprising publisher, and which should contain hygienic rules, first help in accidents, antidotes for poisons, etc. Such a publication might be paid for by advertisements, and would be likely to do much good.

Prof. Maisch concluded by stating that the most

effectual method of securing all the advantages of American pharmacy to public health would be to insure the proper qualifications of the pharmacists. This is one of the main purposes of the local Pharmaceutical Association, and of the national representative body of pharmacists. To accomplish this, among kindred objects, those societies have earnestly labored for years, and in their efforts deserve the support of all having the welfare and safety of the public at heart.

Prof. Gross then introduced resolutions relative to the establishment of a National Bureau of Health.

Among the various matters of business transacted on Friday morning may be mentioned the appointment of committees on the Use of Poisons and on National Sanitary Information, and also a special committee to devise a project of laws to meet the wants of the State Boards of Health.

The following officers were then elected for the ensuing year:

President, J. M. Toner, of Washington, D.C.

First Vice-President, E. M. Snow, of Rhode Island.

Second Vice-President, Prof. Henry Hartshorne, of Philadelphia.

Secretary, Elisha Harris, of New York.

Treasurer, John R. Rauch, of Illinois.

Executive Committee, J. S. Billings, U.S.A.; Stephen Smith, New York; Moreau Morris, New York; J. J. Woodward, U.S.A.; James A. Stewart, Baltimore, and A. N. Bell, New York.

The following resolutions were then presented by Dr. Hartshorne:

"*Resolved*, 1. That, for a city properly arranged and conducted, abattoirs, subject to municipal regulations, are always preferable to a number of private slaughter-houses.

"2. That the best practicable management of large abattoirs, with cattle- and hog-yards, cannot be depended upon at all times to prevent their drainage from contaminating water and the atmosphere in its vicinity.

"3. Therefore, such establishments should be located as far as practicable from the centres of population, and, if possible, upon tide-water."

The mover called upon Dr. Rauch, of Chicago, for information relative to his experience in the matter at Chicago. Dr. Rauch said that the many improvements made had done away, in a great measure, with the objectionable features of slaughter-houses; but, under certain conditions of the atmosphere, a whole section of the city would be pervaded with the disagreeable odor. He thought that, as a general thing, the drainage from abattoirs should not be allowed to enter a fresh-water stream, unless the current was very swift. In Chicago the value of property had always been greatly diminished by the establishment of abattoirs, for people kept at a respectful distance from them. He believed, however, it was possible to conduct abattoirs so as not to be injurious to the public health.

The resolutions offered by Dr. Hartshorne were, with some slight modifications, adopted. Dr. Goodwin then presented the following:

"*Resolved*, That this Association urge upon the Governors and Legislatures of each and every State in the Union the importance of enacting laws creating State Boards of Health and providing adequate measures for sanitary administration throughout each State.

"*Resolved*, That a copy of this resolution be forwarded to each Governor and Legislature, duly signed by the President and Secretary of the Public Health Association."

The subject was referred to the special Committee on Legislation.

The Association then adjourned, to meet in Baltimore on the second Tuesday in November, 1875.

BIOLOGICAL AND MICROSCOPICAL SECTION OF THE ACADEMY OF NATURAL SCIENCES.

NOVEMBER 2, 1874.

DIRECTOR W. S. W. RUSCHENBERGER, M.D., in the chair.

DR. J. H. MCQUILLEN, chairman of the committee having charge of the Semi-Annual Exhibition held the previous month, read his report, of which the following is an abstract:

"Mr. Director, and Gentlemen,—In presenting a report of the Microscopical Exhibition given under the auspices of the Section in the Academy, on Monday evening, October 5, 1874, it is but proper to state that it was proposed and agreed upon by the committee, that in the arrangement of the specimens they should be classified in such a manner as to give a comprehensive view of the subjects presented, by bringing objects related to one another under the same head; in this way adding not only to the interest of the exhibition, but also increasing thereby the opportunity of acquiring valuable information on the part of those who would be present. This plan was carried out as far as practicable, and the desired result obtained. The microscopes, forty in number, were arranged on tables in three rooms of the library. The principal, if not the only, drawback of the exhibition was the contracted space, and the impossibility of properly accommodating the large number of persons present.

"Dr. JOSEPH G. RICHARDSON showed the circulation of the blood through the tail of a so-called triton in Holman's siphon life-slide; also five other specimens of blood, among which human and sheep's blood were exhibited under Powell and Leland's dry, and Tolles' immersion one-fiftieth lenses, respectively. Accomplished as this was in a crowded room, where hundreds of persons were jostling against each other, it places beyond a question of doubt the possibility of making a similar demonstration in a crowded court-room, and of not merely satisfying, under such circumstances, the experienced microscopist, but in addition the most ignorant and obtuse jurymen. Made as this was for the first time in public on that occasion, it may be truly said that this demonstration, in connection with his previous valuable investigations in the same direction carried on in the seclusion of his private office, marks an era in medical jurisprudence.

"Dr. J. H. MCQUILLEN had under his care an ingenious class-microscope, loaned to him for the occasion by Prof. Oliver Wendell Holmes, who designed and partly constructed it, and who uses it along with several others in the lecture-room. It is so arranged that transparent or opaque objects can be shown by changing the position of the lamp. He also exhibited a section-cutter, designed by Dr. Edward Curtis, of New York, for making fine sections of soft tissues, and four beautiful sections of the eye, prepared by the same gentleman with this instrument, and kindly loaned by him.

"Dr. W. V. MCCLURE showed nine excellent sections of the eye, chiefly hæmatoxylin, carmine, and osmic-acid stainings of his own preparation, under Hartnack's lenses, from No. 2 up to No. 10, which latter is about a one-sixteenth immersion objective.

"Dr. GEORGE S. ALLEN, of New York, exhibited a specimen of borax by polarized light, using a Herepathite crystal half an inch in diameter, as an analyzer, giving perfect definition under the highest powers, with polarizing properties equal to the Nicols' prism. He also showed the Podura scale under a famous one-tenth immersion Tolles' objective, kindly loaned by Mr. Charles Stodder, of Boston.

"Dr. C. N. PIERCE displayed, among other objects, rotifera in active operation.

"Dr. R. S. KENDERDINE exhibited, for himself and Miss Gerty Bolles, Volvox globator, skin of the sole, and pollen of Hibiscus.

"Dr. C. S. BOKER had on exhibition Hyalodiscus nobilis.

"Dr. ISAAC NORRIS showed two varieties of Brownig's spectroscope, also a specimen of human lung injected, and arranged diatoms.

"Mr. WILLIAM H. WALMSLEY exhibited Müller's new typen-platte, a butterfly's wing, platino-cyanide of magnesium polarized on Crouch's binocular, and Pleurosigma angulatum on Queen's new student's microscope with a one-fifth objective.

"Dr. A. G. REED exhibited very successfully the circulation of blood in a triton under a four-tenths inch lens. This was shown on a circular revolving table, admirably adapted for microscopical purposes. He likewise displayed a very ornamental cabinet for microscopic slides, made of walnut, with boxwood trimmings, and sides of Hungarian ash.

"Dr. J. GIBBONS HUNT showed a number of beautiful botanical slides, double stainings, as follows: 1, common hop (lupulus), showing latex-vessels filled with green color, all other parts violet; 2, cystoliths in nettle (urtica), colored green, and showing filaments attaching them to the cell-wall, all other parts violet; 3, Lygodium palmatum spores and sporangia, all green color, other tissues violet; 4, Woodsia obtusa, theca and spores green; indusium, showing cell-contents; other parts violet. These structures presented every cell distinctly in natural relationship of parts, *without dissection*. The illumination of delicately-stained tissues, especially double stainings like these, by artificial light, is important. The light was concentrated parallel rays, passed through an achromatic bull's-eye lens of least spherical aberration, the best means of displaying such work by artificial light.

"Dr. CARL SEILER exhibited a number of beautiful micro-photographs of his own production; also, under sundry microscopes, fern from the stomach of a mastodon, spinal vessels, isolated and in position, transverse section of elephant's bone, and human liver.

"Drs. T. C. STELLWAGEN and E. L. HEWITT had under their care ten microscopes, with sections of bone and the teeth of man and animals, showing enamel, cementum, and dentine in various phases; the relations of these tissues being made evident to all by means of a papier-mâché model of a molar tooth, twenty times the natural size, the property of Dr. Stellwagen.

"Mr. CHARLES STODDER, of the Boston Optical Works, in compliance with an urgent invitation of the corresponding secretary, sent on a one-fiftieth immersion (elsewhere noticed), and a one-tenth immersion which has been pronounced a very valuable lens.

"Messrs. QUEEN & Co. showed four microscopes, the most remarkable being one of Beck's large best binoculars, made of aluminum, the lightest of its size ever produced, and yet so well balanced as to be entirely firm.

"Mr. JOSEPH ZENTMAYER displayed three microscopes, viz., student's, grand stand, and binocular, the workmanship and execution of which were of the most perfect character."

Dr. J. GIBBONS HUNT commented upon the report, especially dissenting from the commendation bestowed upon the performances of the one-fiftieth objectives of Powell and Leland, and of Tolles, and also from the favorable notice given to the Tolles' one-tenth immersion, which, he stated, was probably in reality only a one-eighth lens, inferior in power to Beck's one-tenth.

Dr. JOSEPH G. RICHARDSON read a paper entitled "Notes on the Performances of Two One-Fiftieth Objec-

tives" (see p. 132), which was referred to a committee composed of Drs. J. G. Hunt, I. Norris, and J. Tyson.

Dr. JAMES TYSON remarked that whilst it was certain that the difference in size of the corpuscles of human and sheep's blood then exhibited on the table under the two fiftieths by Dr. Richardson was quite perceptible, yet so different did the red blood-disks appear beneath these objectives from what they did under the powers he had ordinarily used, that he would hardly be willing to say that they were blood-corpuscles, if he were ignorant of their true nature.

Dr. RICHARDSON said that in these specimens, only this very difference in size was intended to be shown; the problem he had set himself to solve in *this particular instance* being whether among corpuscles known to be those of blood (by the revelations of moderate powers of the microscope, aided by chemical tests for example), we could make a differential diagnosis by the size alone between those of man and those of the sheep.

Dr. J. GIBBONS HUNT observed that, putting aside the acrobatic feats of the one-fiftieth in the resolution of diatoms by very oblique light, he had yet to see any good definition by it upon an object axially illuminated. As displayed before him, he thought that the two one-fiftieth objectives showed conclusively that no gain in real histological work is secured by using lenses of high power, which afford such imperfect definition, and are by no means achromatic.

Dr. J. H. MCQUILLEN stated that he had purposely avoided expressing any opinion in regard to the one-fiftieth, as Dr. Richardson had prepared a paper upon its qualities. With respect to the objections which have been advanced, that spherical and chromatic aberration had not been entirely corrected, the question arose, If this be true, is the instrument therefore useless? The fact that with it, and the one-fiftieth of Powell and Leland, the difference in size between the blood-corpuscle of man and the sheep was defined in the presence of a crowded audience, in the most unmistakable manner, indicates that it is not *useless* but *useful*. It must not be forgotten that Sir Isaac Newton long ago asserted that it was impossible to construct an achromatic telescope or microscope; and yet, with the imperfect instruments used prior to and during his time, important and valuable discoveries were made by astronomers and microscopists; some of which, observers with the improved instruments of our own day have only confirmed. It was, he believed, assuming too much to say that the one-fiftieth could not be used to advantage in histological investigations. By its aid, in the not far distant future, important and valuable discoveries might possibly be made.

Dr. HUNT granted that the difference in size of the two kinds of blood-corpuscles shown upon the table under an amplification of twenty-five hundred diameters was sufficiently demonstrated, and that therefore it was obvious that high magnifying power had been obtained; the difficulty which we now needed to have overcome was bad definition. As yet spherical and achromatic aberration were not, in his opinion, fully corrected in these high objectives, although opticians were trying to sell them as being perfected. Indeed, no perfectly achromatic lens has so far ever been constructed, so that Sir Isaac Newton's prophecy still holds good up to the present day.

Dr. RICHARDSON desired in this connection to call particular attention to the statement in his paper, that the longitudinal lines of *Surirella gemma* were clearly visible under the one-fiftieth, because with his scanty knowledge of the tricks of illumination by oblique light he could only bring them rather imperfectly into view with the Tolles' one-tenth, which had been pronounced by high American and English authorities—

such as Col. Woodward and Mr. Wenham—a superior lens.

Dr. HUNT reminded the members that these lines and those of other difficult diatoms could all be resolved, by even lower powers, with perfect ease.

Dr. RICHARDSON replied that this easy resolution of difficult diatoms under low powers certainly required a greater skill in the management of the light than he possessed, since he had completely failed in repeated attempts; and yet, with exactly the same ignorance of these ingenious artifices as stated above, he brought the fine lines (of which he had almost begun to doubt the existence) clearly and sharply into view at the first trial by monochromatic sunlight with Tolles' immersion fiftieth. Moreover, he felt sure that any unprejudiced microscopist would perceive that a lens which was capable of showing the finest markings on the Diatomaceæ as distinct lines or dots must be similarly capable of showing analogous delicate lines and dots in the cells, fibres, and membranes of human and animal tissues; and since these lines and dots *make up absolutely all that we know of the morphological characters of histological elements*, lenses which, like the one-twenty-fifth and one-fiftieth, show finer markings, will almost necessarily prove of greater practical value in histological research.*

REVIEWS AND BOOK NOTICES.

A GUIDE TO THE PRACTICAL EXAMINATION OF THE URINE, FOR THE USE OF PHYSICIANS AND STUDENTS. By JAMES TYSON, M.D., Hospital Lecturer on Pathological Anatomy in the University of Pennsylvania; one of the Physicians and Pathologist to the Philadelphia Hospital, etc., etc. Pp. 182. Lindsay & Blakiston, Philadelphia, 1875.

Almost every one of our seventy thousand practitioners of medicine feels at times the want of a reliable guide to the more complete examination of the renal secretion in cases of doubt and difficulty; and since this book admirably meets just such a universal necessity, we are convinced it will find a multitude of readers in all ranks of the profession. Being a larger and more exhaustive work than those of Flint and Wickham Legg on the one hand, and, notwithstanding it sets forth the valuable German methods of approximative and exact quantitative analysis, less cumbrous or expensive than those of Beale, Roberts, Harley, etc., on the other, we welcome it as an important aid towards wider cultivation of the true science of medicine by facilitating accurate investigations of the urine even among busy physicians in general practice.

Dr. Tyson commences with a short account of the theory of renal secretion, the physical and chemical characters of the urine, and the reagents and apparatus used in its analysis. Excellent rules are then given for detecting the presence of albumen, sugar, coloring-matters, bile, urea, uric acid, chlorides, phosphates, and sulphates; and minute instructions for approximative and quantitative determination of most of those ingredients by volumetric analysis are supplied.

* It is well known that some cases occur where a diagnosis between cancer-cells and the cells of vesical epithelium would be important, and this, if ever accomplished, will, perhaps, be made by the discovery of some finer markings upon one or the other morphological elements than have yet been described.—the process being comparable to that by which we would distinguish between twin brothers at the distance of say one thousand feet, when by a telescope of moderate power we might recognize the outlines of their features and guess which was Castor and which Pollux, but with a very powerful optical instrument—the analogue of a one-fiftieth objective—which would *define delicate lines*, we might count the eyelashes of each, and, on a previously known difference in their number, base an accurate differential diagnosis.

The subject of urinary deposits is carefully treated of in the remaining seventy pages of the volume, being illustrated by a plate and numerous wood-cuts representing the microscopic characters of various crystalline sediments, and also the organized constituents, such as mucus, pus, and blood; a proportionately large space being duly allotted to the important subject of tube-casts in Bright's disease. A few pages upon the differential diagnosis of the forms of albuminuria are added, and constitute, in our opinion, the most admirable, as well as the most practically useful, chapter in the entire book.

About half the wood-cuts—thirty, or rather twenty-nine in number, since Fig. 14 only differs numerically from Fig. 10—are given as original, and the remainder have been well selected from the works of Harley and others. In our opinion their value would have been much increased had those representing microscopical appearances been furnished, as is always done by Dr. Beale, with a statement of the magnifying power under which they were drawn.

The author's style is generally perspicuous; concise, definite, and easily comprehensible statements being usually made in regard to the subjects treated of, although occasional infelicities of diction occur. For example, we should prefer an Anglicized version of the following, on p. 21: "Requiring an acid urine to keep them (earthy phosphates) in solution, a diminution of the degree of this may result in their precipitation, which is further increased by an alkaline reaction."

The lithographic plate, exhibiting very accurately the usual appearances of the so-called pigment-flakes, or pigmentary particles, has a peculiar interest, and will doubtless prove very useful in explaining one of their common puzzles to students, as well as in preventing them from falling into the lamentable yet ludicrous blunder of Dr. Roberts and others in regard to these microscopic dirt-pits upon the glass slides.

The Table of Contents is omitted, and obvious misprints occur on pages 28, 48, 92, 146, and 162, but the book as a whole is remarkably free from typographical errors, and shows the results of that faithful and painstaking carefulness which so eminently characterizes its learned author.

In paper, press-work, and binding, the volume will well sustain the high reputation of the distinguished medical-book publishers whose imprint it bears.

J. G. R.

GLEANINGS FROM OUR EXCHANGES.

OCCIPITO-POSTERIOR POSITIONS OF THE HEAD (*The Edinburgh Medical Journal*, October, 1874).—Dr. Angus Macdonald, as the result of an analysis of twenty-six operative cases, has arrived at the following conclusions:

1. In occipito-posterior positions, if these are persistent, we may safely assume that we have some pelvic peculiarity or disproportionately large head to deal with, and, as a general rule, all attempts at artificial rectification of the position of the head will prove abortive, and are even dangerous if attempted to be effected by means of levers, forceps, etc.

2. The only exception is when temporary delay is occasioned from accidental displacement of a small head; in which case one has the alternative of waiting till the normal powers of parturition effect delivery, or of facilitating that event by timely rectification of the head by the hand.

3. In cases which threaten to end as "face to pubes," and are at the same time decidedly difficult, it is best to pull the head through cautiously, and to abstain from every attempt at rectification of the head,—special

care being taken to guard the perineum, as the occiput, when passing over it, greatly distends it.

4. In cases of obstructed occipito-posterior positions, in which the rotation takes place at the outlet of the bony pelvis, while the head is in the grasp of the curved forceps, there is very great danger in the case of primiparæ of the forceps lacerating the soft parts, on account of the oblique position into which they are thrown.

5. To prevent this accident, either, 1, the blades ought to be cautiously removed, the head fixed in position, and the uterus allowed to finish the expulsion of the head; or, 2, the curved instruments may be reapplied, adjusted to the altered relation of parts; or, 3, a straight, short pair may be applied, and the further advance of the head thereby secured.

RENAL CALCULUS (*The Lancet*, October 24, 1874).—At a recent meeting of the Pathological Society of London, Dr. Cayley showed a renal calculus which was discharged through a fistulous opening in the loin. The patient is now 33 years of age, and in good health. Seven years ago he suffered from an abscess in the right lumbar region, which discharged for about three years. About six months after its formation, the calculus came out. It was of irregular club shape, the size of a hazel-nut, with a facet at the narrow end as if it had been broken off. Two smaller calculi subsequently ulcerated out, one close to the crest of the ilium, and one below the great trochanter, the scars still remaining. The patient was employed at chemical works where sulphite of arsenic is made, and it was a question whether there was any genetic influence in his occupation.

UNSUSPECTED CALCULI IN THE BLADDER (*The Lancet*, October 10, 1874).—Mr. John Foster reports the case of a gentleman, æt. 76, who had a narrow stricture at the orifice of the urethra. He had considerable frequency in making water, but had suffered no pain, and never passed any blood. The stricture was divided, and a catheter introduced to ascertain if he emptied his bladder. With the urine came a large number of very small calculi, and, by injecting warm water, over a thousand were washed out. They had never caused him any inconvenience.

NOTES AND QUERIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

DR. H. Y. EVANS will read a paper before the Philadelphia County Medical Society, November 25, 1874, at 8 o'clock P.M.

Subject, Rest in the Treatment of Pulmonary Disease.

All regular practitioners of medicine in the city are invited.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM NOVEMBER 17 TO NOVEMBER 23, 1874, INCLUSIVE.

HUBBARD, VAN BUREN, ASSISTANT-SURGEON.—Assigned to duty at Jackson Barracks, La. S. O. 187, Department of the Gulf, November 17, 1874.

KINSMAN, J. H., ASSISTANT-SURGEON.—Relieved from duty at Fort Abercrombie, Dakota Territory, and to report in person at these Headquarters. S. O. 252, Department of Dakota, November 16, 1874.

CRONKHITE, H. M., ASSISTANT-SURGEON.—When relieved by Assistant-Surgeon Dickson, to comply with War Department Orders 233, c. s. S. O. 186, Department of the South, November 17, 1874.

YEOMANS, A. A., ASSISTANT-SURGEON.—Granted leave of absence for three months, on Surgeon's Certificate of Disability. S. O. 250, A. G. O., November 17, 1874.

DICKSON, J. M., ASSISTANT-SURGEON.—Assigned to duty at Savannah, Georgia. S. O. 186, c. s., Department of the South.

JOHNSON, HENRY, MEDICAL STOREKEEPER.—Granted leave of absence for three months. S. O. 253, A. G. O., November 20, 1874.

SATURDAY, DECEMBER 5, 1874.

ORIGINAL COMMUNICATIONS.

SOME REMARKS UPON THE RELATIVE STRENGTH OF CHLOROFORM AND ETHER, WITH HINTS UPON THEIR USE AS ANÆSTHETICS.

BY OSCAR H. ALLIS, M.D.,

Surgeon to the Presbyterian Hospital.

Read before the Philadelphia County Medical Society, October 14, 1874.

MR. PRESIDENT and Members of the Association. Gentlemen: Desirous of fulfilling, so far as I may be able, the obligations assumed in becoming a member of this Society, I have cheerfully, though with many misgivings, complied with a request from your Secretary to present a subject for this evening's consideration. I have chosen *the administration of anæsthetics*, a subject that must continue to be of interest while pain and disease are the heritage of man. But I am frank to confess that I introduce such a subject before this Society with very many misgivings, as some of your members have been familiar with these agents since their introduction to surgery. There is, however, in this a compensating pleasure, that we will have the advantage of listening to these gentlemen after my brief remarks are ended.

My practical experience with anæsthetics began with my appointment to the surgical clinic in the Jefferson Medical College in 1867. Here, through the kindness of the Professor of Surgery, I was given in charge of the chloroform, and for more than two years assisted him in that capacity in his public and private labors. I look back upon the discipline of those years as among the most valuable of my life. Professor Gross is a firm believer in the superiority of chloroform over all other anæsthetics, is careful to instruct his assistant in its use, and then gives him to understand that his duty is *wholly with the chloroform,—that he has no other duty,—and this duty he expects him faithfully and conscientiously to fulfil.* Herein lies the "good luck" of Professor Gross. I know of no other way of accounting for it; for at a public clinic, where every age and condition of life presents itself, one has certainly every right to look for disasters, and yet in all my service with him I recall but a single instance of apparent danger. A female, whose surgical malady was complicated with phthisis, was about to be operated upon, and, as she was tardily influenced by the chloroform, an assistant dashed on the towel a quantity from a bottle that would hold two pounds. The result in this case gave some alarm, and taught me—

1. Never to be in a hurry to effect anæsthesia.
2. Never to use a large quantity when the patient is nearly influenced.
3. To use a small vial, from which a small quantity can be dropped, and that quickly.

From this time forth I began to influence my

cases rapidly, and with very little chloroform; but when it occurred to me to make some observations upon the amount necessary to effect anæsthesia in ordinary cases, the result was the construction of the following apparatus:

It consists merely of two tin cones soldered apex to apex, with a tube projecting from the upper or receiving cone into the lower. Around the base of the larger cone a piece of linen is tied. When the instrument is to be used, a towel is properly folded and pinned around the larger cone, presenting, when complete, a cone of sufficient size to cover neatly the mouth and nose. This cannot be called an inhaler with

any more propriety than can a towel or a napkin; but, while it resembles the latter in principle, it has in practice very many and important advantages.

1. The chloroform falls through the tube (Fig. 1) upon a single layer of linen (a), to both sides of which the air has ready access, and is accordingly instantly evaporated.

2. Every drop is conveyed to the patient.

3. A *few drops* at a time are all that are ever required, and all the patient can breathe with comfort.

4. The dropping may be more or less constant, as the instrument need not be removed from the face, and by means of a "dropper" the operator can gauge the amount to the necessities of the case.

5. The anæsthetic influence is gained gradually, imperceptibly, and rapidly, and with a minimum amount of chloroform. I seldom use more than a drachm and a half in adults.

6. As only a few drops need be added at a time, the danger must be far less than when an indefinite quantity is poured on from a bottle at once.

7. There is no exclusion of the air, but the air that is breathed is impregnated with a fresh supply of chloroform.

8. The time consumed is usually from three to ten minutes.

9. The influence once obtained may be easily maintained.

I have used this repeatedly for nearly two years, and have found it all that I could desire. It is exceedingly convenient as a frame-work about which to pin the towel, and as a receiver of the chloroform, and so simple in construction that any tinsmith could repair it should it be broken.

As to its rendering the use of chloroform safe, I can only say that *safety does not lie in an inhaler*, but in *him who uses it*. I think, however, it is far safer to produce anæsthesia by an equal and constant supply of chloroform, *i.e.*, drop by drop, than by pouring it on *at intervals*, and in quantities even so small as half-drachms at a time.

When I use it, I drop my chloroform from a graduated bottle containing three drachms; and the operation must be long and severe that will require a refilling of my little vial. The whole apparatus is calculated to render one most watchful.

The facts that he holds in his hand a vial with three drachms of chloroform, a drachm and a quarter of which, properly used, is to effect complete anæsthesia; that every drop of the chloroform goes to his patient, and that to effect his purpose the supply must be constant; that as he watches the dropping he watches also its effects upon his patient,—such thoughts must, I say, keep the administrator on the alert, and he who watches his patient with such care will not often be embarrassed by unpleasant symptoms. *Too much care cannot be exercised by the chloroformist*, since Simpson says of it, "I have known seven inspirations from thirty drops to place a strong man perfectly under its influence."

As soon as I had satisfied myself with chloroform, I turned my attention to ether. In children, and in some females, I could effect rapid anæsthesia with the apparatus; but in the majority of cases I found it unsuitable. With it I could not give ether fast enough. One strong man to whom I was administering it kept repeating, "Give it to me faster; pour on the whole bottle," though I was pouring it on at the time in a constant stream, and it was running down the edges of the towel. To satisfy myself about it, I frequently inhaled it, and experienced the same desire for *more ether*. This experience suggested to me the necessity of a larger evaporating surface, and, as a result, the following apparatus.

It consists of a wire frame-work, sufficiently large to cover the lower part of the face. The wires are

FIG. 2.

parallel, and about an eighth of an inch apart. Between the wires, from side to side, a strip of bandage two and one-half inches wide is passed. By reference to the figure (Fig. 2), the manner in which this is accomplished will be readily understood. Upon the right, a part of the wire framework is purposely left exposed to show the manner of its construction. The instrument is only about four inches long and three inches at its greatest width, and yet it consumes nearly three yards of bandage when passed between all the wires. By further reference to the figure, it will be seen that each section of the bandage is separate from the adjoining one, thus permitting the air to pass freely to both sides of it. When ready for use, the sides are covered, but the top is left open for the free entrance of air and for convenience in supplying the ether. I usually supply the ether from a gradu-

ated bottle furnished with a dropper-cork (Fig. 3), as by such a convenience I can add the ether as gradually or as rapidly as the case may demand.

My mode of using it is as follows. Placing it over the face, I sprinkle on *a few drops* of ether,—I mean literally but a few drops. In a few seconds I add a few more drops; and usually in from half a minute to a minute I find that I can drop it more constantly. As soon as I notice *the deep inspirations* I pour on a small stream, watching carefully lest I irritate the larynx, and as soon as I find the patient tolerant of its vapor I add it in larger quantities, and as rapidly as can be evaporated, and am usually gratified by seeing my patient pass *quietly* under its influence in from three to ten minutes.

Now, it may be asked, what advantages does this possess over the towel and sponge? First, let me speak of the disadvantages of the towel and sponge. The towel is usually fashioned into a cone, and placed in a similar cone of paper. The object of the paper cone is to prevent the evaporation of the ether, *so that the patient will get it all*. Now, it is quite certain that the patient does get all the ether, and that by means of the paper cone very little can escape. But it will be noticed that there is left but a very small evaporating surface, for the *inner surface* of the towel mainly yields the ether; and it is still further true that the more rapidly the ether is poured on—*i.e., the more fluid ether there is in the meshes of the towel—the less rapidly is the vapor of ether evolved*. The reason of this is obvious upon a moment's reflection. The moment the ether is poured on liberally, the towel becomes wet with it; its various folds, lying in close contact with one another, are filled with fluid ether, and it may not inaptly be regarded as a solid mass of ether, whose evaporation is only possible from the inner surface of the towel. This is a matter of easy demonstration. Take, for instance, two towels; fold one into a cone, and, investing it with a paper one, pour on an ounce of ether. Take another towel, and, suspending it so that its entire surface is exposed to the air, pour on a like quantity. The latter will be dry, and there will not be a trace of ether left in a minute's time; while the former will be damp and cold, and yield a strong odor of ether for at least five minutes.

With the sponge it is even worse. The sponge usually recommended is the finest that can be found. The pores, so to speak, are very small, and when two or three ounces of ether are thrown upon it it becomes a mass of liquid ether, with an exceedingly small evaporating surface, and hence wholly unfit for the rapid disengaging of the vapor of ether.

I return now to what I think I may in all fairness claim for the apparatus.

1. It possesses a *large evaporating surface*. You will remember that it consists of a bandage three inches wide and one hundred inches long, so arranged that in its entire length no fold touches its fellow, and with a free access of air to all parts of it. As compared with this, the evaporating surface of the towel or sponge is very small.

2. With a large evaporating surface there must be rapid evaporation of the ether, and consequently rapid anæsthesia. I have placed patients under its

FIG. 3.

influence in three minutes, seldom requiring ten minutes.

3. With rapidity of evaporation may be associated *economy* of ether. I usually require less than *two ounces* in adults, and rarely three ounces.

4. There is no exclusion of the air, and no unpleasant laryngeal irritation. I have rarely had a patient cough or spit during the administration, and it is extremely rare for patients to remark upon its unpleasant odor or object in the least to inhaling it.

In this respect it presents a marked contrast to the mode commonly adopted. It is usually considered important to exclude the air, and to give the patient "nothing but ether" to breathe. The result is that the patient resists as for life, and is only overcome by superior numbers.

Lastly, the inhaler need not be removed from the face; and, the supply of ether being constant and fresh, the patient passes under its influence quietly, —often without a struggle. Even after I have effected complete anæsthesia I continue adding it in small quantities, —a few drops at a time, —watching the degree of effect, which is usually indicated by the character of the respirations. A little experience will enable one to maintain throughout an entire operation a uniform degree of anæsthesia, —a condition very gratifying to the surgeon.

But an inhaler is not a convenient thing to carry with one in private practice; and, as a towel is usually to be had, allow me to make a suggestion in regard to folding and using it. (1) Spread out the towel, and over it place a newspaper of the same size; (2) make two folds of it lengthwise, the paper being folded within; (3) now double it again, so that it will be about ten inches long and eight wide; pin this into the shape of a cone. If, now, you examine this, you will find that there is but a *single layer* of the towel that can be wet with the ether, as the next layer is paper. Now, use this with the same care that I have enjoined in using the inhaler. Begin with a few drops, and add no more than *a few drops at a time* until the patient has become accustomed to the vapor, and then never add more than *a drachm at a time*, and be sure that this drachm is sprinkled over a broad surface. The supply of ether must now be quite constant; therefore, two or three times a minute *sprinkle* on a drachm, taking care not to *wet* the towel by adding a large quantity at a time, and you will be amply repaid for your pains in seeing the ease with which you effect your purpose.

As to sponges, a fine sponge is the worst thing that can be selected. The coarser the sponge, the better it will be found to be adapted for the purpose.

I will here insert the more important rules laid down by those most experienced in the use of anæsthetics. There should be no possible barrier to the freest respiration. Among the fatal cases from chloroform, one is recorded where "the necktie was removed as soon as the man became blue in the face."

The stomach, as a rule, should be nearly or entirely empty. If the stomach is distended either from food or drink, vomiting will almost invariably ensue, and

vomiting when the patient is narcotized from any cause is not unattended with danger. Among the cases put down as deaths from ether will be found those that really are due to vomited matters passing into the trachea.

Often when the patient shows a disposition to vomit it may be averted by hastening the anæsthetic effect, and this is especially true of ether; but when vomiting is inevitable, the patient should be placed in the most favorable position for the escape of the contents of the stomach. It is not enough to turn the head to one side; the body should be turned on the side, and then the slight turn of the head downwards will be sufficient for all practical purposes.

It is strange how often this precept is violated. In one case, however, I even saw a doctor put his hand over the patient's mouth, to prevent the contents of the stomach from escaping upon the bedding.

*There is but one posture for the administration of chloroform, and this is the reclining. From this rule there is no safe departure.** Many of the fatal results from its use are from neglect of this cardinal maxim. Ether, on the contrary, knows no such law. When, however, the erect position is desired, let the anæsthetic be induced in this posture, for I question the safety of raising a patient thoroughly anæsthetized in the reclining posture to the erect. If the etherization is begun in the erect posture, its progress can be watched, and, in case of danger, the position can be changed.

The *degree of narcotism* will depend upon the object for which the anæsthetic is administered.

It is a well-known fact that a patient may cry and moan through an entire operation, and yet remember nothing of it at the return of consciousness. But the rule is, and it is founded upon the experience of surgeons, that severe operations should not be undertaken without first securing a profound impression from the anæsthetic.

Lastly. Leave the patient under the care of a competent, faithful attendant, with positive orders not to leave his presence until the effects of the anæsthetic have passed away. One of the most distressing cases that I have ever read was that of a man who had been operated upon for strangulated hernia, who, waking from the operation, snatched away the dressing and tore out in his frenzy yards of his own entrails.

Some begin with ether, and bridge over the exciting stage with chloroform. I would be afraid of this "bridge." Its farther side might be in eternity, —since it is nothing less than using a ten-fold more dangerous anæsthetic at the moment when danger is most imminent.

Out of one hundred and sixteen deaths from chloroform, three-fourths (88) occurred in this very stage of excitement.

Others use a mixture consisting of two parts of ether and one of chloroform. This is called chloric ether. This is used very generally by dentists, and

* As the design of this article is merely to offer a few hints upon the administration of anæsthetics, no theories are offered for the action or fatal results of the agents.

in the sitting posture. An ounce and a half of this mixture is usually sufficient to effect the desired purpose, *but its use cannot be too strongly condemned.* This ounce and a half, you must bear in mind, has half an ounce of chloroform, *and this is given in the sitting posture! and as freely as if it were only ether!*

"In the mixture of chloroform and ether, we have no definite chemical compound formed. When the mixture is exposed to air, the proportion of the ingredients is continually changing by the greater proportionate loss of the more volatile body, and it is quite impossible to apply any formula by which we can judge of the comparative rate of evaporation of the two ingredients."*

The union of the two ingredients may properly be called a mixture, and the mixture remains constant so long as it is excluded from the air; but the instant it is used for the purposes of anæsthesia, the more volatile ether first escapes, leaving behind it the more powerful but less volatile chloroform. I must not be understood as saying that the vapors do not mix; they certainly do pass off simultaneously. Nor can they be said to separate. But the important fact that the boiling-point of the two liquids is so different—the ether boiling at the temperature of the body, *i.e.*, 96° Fahr., while chloroform boils at 142° Fahr.—must render the mixture on exposure to the atmosphere a very inconstant one, and especially so when warmed by the air from the lungs.

Whoever, then, uses the mixture may depend upon it that the effect he gains is chloroformic; and let him proceed with corresponding caution.

I should not question the statement of any one who would say that he had produced perfect anæsthesia with a drachm and a half of the mixture (*i.e.*, 3ss of chloroform and 5j of ether), since Dr. McDowell, Professor of Surgery in Trinity College, says of chloroform, "I have known thirty drops to suffice."

Statistics show that there is one death in 5588 administrations of this combination, making it but little less than half as fatal as chloroform alone.

But I may be asked to express an opinion as to the relative safety of the two anæsthetics.

I was fortunate enough to give chloroform and ether to five persons under similar circumstances, and found by comparison that chloroform—drachm for drachm—was eleven and four-sixths times stronger than ether. In comparing ten cases as nearly alike in age, sex, and strength as I could, I obtained a similar result.† But the relative energy of the two anæsthetics will appear to a greater advantage if we recall the mode of their administration: with chloroform it was sufficient to moisten, drop by drop, a surface about three inches square; while with ether to accomplish the same result a surface three inches wide and sixty long was required.

Herein will be noticed a very surprising difference between the two anæsthetics, and to the reflecting mind this will convey a most important lesson, and

suggest a possible explanation for the sad contrast in their career. In less than a quarter of a century, hundreds of unfortunate human beings have met, through the agency of the one, a sudden and appalling death; while with the use of the other, safety is guaranteed with the most ordinary care.

But I will not do chloroform the injustice to say that the guilt is wholly its own. Four thousand cases,‡ representing every phase of society and embracing every age and condition of body, are proof against such an attack.

At whose door, then, lies the blame? Partly at its own, but mainly, I believe, at the thresholds of its adherents.

I say partly at its own door, for I do not think that any one has ever yet ascertained the lethal energy of chloroform. I am confident that I can influence the *average adult patient with less than a drachm and a half of chloroform.* Of this amount, scarcely a third accomplishes its mission; the other two-thirds are lost. Hence, I say, to the energy of the agent itself may be attributed a part of its fatal consequences. In the *Lancet* is a case where twenty minims are said to have caused death. Once I could not have believed this; but the more I employ chloroform the more I am struck with amazement at its magical powers.

But I have charged the disastrous effects of chloroform mainly to those who administered it. Kidd long ago noticed the significant fact that ninety per cent. of the deaths from chloroform were during trivial operations, and he was not backward in assigning the true reason. He says "that chloroform is given into the hands of *hospital-dressers, students, and female nurses*, and that minor operations are usually undertaken without a due corps of competent assistants."

Very few taking charge of the anæsthetic have the least conception of the responsibility of their post. They seem to feel that they must *sponge, control hemorrhage, hand instruments, and have a general supervision of the case, or they are not really useful.* An interne in one of our hospitals is reported to have left the towel over a patient's face and to have gone into an adjoining room for a needed article; and once while I was operating for a friend he left the towel over the patient's face, and came around the bed to see the progress of the operation.

How often have physicians gone *alone* to their patients, because the patient objected to having a "strange doctor" present, and there for some trifling operation administered chloroform, assisted only by persons ignorant both of the agent and of the approaches of danger! I was never frightened but once in the use of chloroform, and that was in the case of a lad whose knee I wished to examine under its influence. Having induced anæsthesia, I handed the towel to a female attendant who had assisted me before in the same capacity. The lesson was a fearful one; and had my patient died I might have been fortunate enough to find a "fatty heart," but

* Dr. Henry Leffmann.

† Snow says that chloroform is more than ten times stronger than ether by measure.

‡ Record of Prof. Gross. See Principles of Surgery, under Anæsthetics.

never after would my conscience have been free from remorse.

While, then, I would exonerate chloroform from the charges that have been laid upon it, I cannot, with the fearful list of casualties before me, do less than express a deep regret that it is still so extensively used by the profession. That it possesses certain advantages over ether, I am fully aware; but that these advantages are greatly magnified, I do not hesitate to affirm. In my own experience I have not found ether more irritating to the larynx, more tardy in its effects, or more likely to produce delirium, than chloroform. I make these statements after a long and faithful experience of both of these agents, upon myself and upon others, and I feel confident that others will experience like results if they will once *learn how to give ether*.

Study; then, the nature and effects of ether. It presents not a single physiological difficulty that care and experience will not overcome; and, when you have once obtained *the secret*, you will feel amply repaid in the security of your patient, and in the fact that you may give your whole attention to your own procedure, without the furtive, anxious glances that are necessary to the successful employment of chloroform.

CASES OF HYDROCELE COMPLICATED WITH VARICOCELE AND CYSTOCELE, TREATED WITH ERGOTIN AND TINCTURE OF PERCHLORIDE OF IRON.

BY CHARLES D. GREEN, M.D.,
Philadelphia.

CASE I.—*Hydrocele of the tunica vaginalis, and encysted hydrocele of the spermatic cord.*—S. B., aged 19 years, resident of Philadelphia, came under my care Jan. 2, 1873. He had always enjoyed good health, with the exception of having had for the last nine years a hydrocele of the right tunica vaginalis. Twelve months previous to seeing me, the swelling had attained the size of the doubled fist, and the radical treatment for hydrocele was resorted to with apparent success, injection of iodine being used. Some time after, however, a small swelling appeared in the upper part of the scrotum, and gradually increased in size to that of a turkey's egg, lying in front of the pubes, in the site of the external abdominal ring, passing somewhat into the inguinal canal, and also down towards the testicle, which could be distinctly felt in the lower part of the scrotum. The swelling could be pressed slightly downwards or upwards; there was no indication of hernia, no remarkable impulse on coughing; no alteration in size or position as the patient altered his attitude, and when a candle was used the tumor was seen to be transparent. He had been refused admission to the naval service in consequence of his affection, and was anxious for a cure.

Jan. 4.—With a small trocar and canula about six ounces of clear-colored fluid were drawn off, and one grain of ergotin, with twenty drops of distilled water, injected into the sac and allowed to remain. The canula was then removed, and cold applications ordered in case of too much heat and tenderness.

5th.—Patient had not suffered much, though there was considerable swelling of the whole scrotum.

9th.—Since the 6th, the swelling had diminished almost entirely. In the site of the original disease there was a hard, firm mass, about the size of an almond.

10th.—Dismissed, cured. Saw him in June last; parts were normal.

CASE II.—March 13, 1874. *Hydrocele complicated with epiplocele, etc.*

A ship-carpenter, temperate, and of strong fibre. Twelve months previous to consulting me, an inguinal hernia appeared on the right side, which, after application of leeches while the patient was in the horizontal position, returned spontaneously. Subsequently it often came down, but it was speedily reduced by change of position. Six months before my seeing him, on one of these occasions, it could not be returned, although leeches and cold and warm applications were had recourse to, and the swelling remained in the canal and superior part of the scrotum. At the bottom of the scrotum was another swelling, about half the size of the first, soft, elastic, and transparent, seemingly quite distinct from the one above, and presenting all the characteristics of hydrocele. The upper swelling was soft and doughy in feel, and all attempts at pushing the protruding parts into the abdomen were abortive. The patient was desirous of proceeding on a long voyage, and anxious for something to be done before he left, as he felt some inconvenience from the size of the scrotum, produced by the two swellings.

On puncturing the lower part of the scrotum, about twelve ounces of clear-colored fluid was drawn off, but no change was perceptible in the upper part of the swelling. Three-fourths of a grain of ergotin and twenty drops of distilled water were injected and allowed to remain. Immediately after, he experienced a smarting pain in the testicle and some uneasiness in the abdomen. Both, however, subsided after a couple of hours.

16th.—He had had no return of the pain, and the swelling was nearly the size it was before the operation, but free from pain or tenderness. Ordered to remain in bed and continue to support the part in a sling.

19th.—Swelling was almost entirely gone; testis could be felt distinctly, of its natural size and in a healthy condition. Dismissed, cured.

CASE III.—*Hydrocele (of tunica vaginalis) complicated with varicocele.*—Jas. H., aged 73, consulted me April 15, 1874 (a lawyer, of temperate habits, rarely ever sick, and active for his age). Four months previous to seeing me, after a trifling strain in lifting books, he first noticed an unusual enlargement of the scrotum, observable during the day, but disappearing in the course of the night. In about a fortnight it became stationary, and remained so up to seeing me, excepting that it was gradually increasing in bulk. The scrotum was about the size of a quart jug, and of a pyriform shape, the skin very tense; the swelling, which was on the left side, extended as high as the external abdominal ring, and had all the ordinary indications of hydrocele of the tunica vaginalis.

April 16.—Scrotum was tapped, the fluid amounting to over two and a half pints, and one grain of ergotin and twenty drops of distilled water injected into the sac and allowed to remain.

18th.—There was considerable effusion since the 16th; scrotum red and tender.

20th.—The later symptoms ameliorated; but the effusion as great as on the 18th.

21st.—Swelling much less, and appeared to depend as much on the enlargement of the veins of the scrotum as on effusion in tunica vaginalis.

22d.—Effusion gone; veins of scrotum enormously enlarged. Injected two drops of tincture of perchloride of iron at three points in the varices, strapped the scrotum, removing the strips the next day; the points of punctured veins were hardened, but showed no active sign of inflammation; no dressing other than supporting the scrotum was used.

24th.—Dismissed.

Saw this patient in August last. No sign of hydrocele or varicocele, the dartos keeping the scrotum well corrugated.

Case IV.—Hydrocele (of the tunica vaginalis) complicated with cystocele, treated with ergotin and perchloride of iron.—John L. J., from Dover, Del. (a tiller and hedger), æt. 62, temperate habits. Five months previous to seeing me, while getting out timber, he felt something suddenly give way in the left groin, not followed by much pain, but by a large swelling of the scrotum.

June 18.—Scrotum tense and painful on pressure, and elastic; testis occupying the anterior middle, the swelling presenting more the appearance of hæmatocele than of hydrocele. Drew off fourteen ounces of chocolate-colored fluid, and injected half a grain of ergotin, with twenty drops of distilled water; allowed to remain. No severe pain; further examination revealed unusual enlargement of the spermatic veins; testis of usual size, and apparently healthy.

19th.—Effusion as great as at the time of tapping yesterday, but no redness or pain except near the external abdominal ring.

21st.—Effusion gone, but some tenderness in the course of the spermatic cord.

23d.—Could distinctly feel and separate the veins from the vas deferens. Having applied a compress over the pubes, injected two drops of the tincture of perchloride of iron in the middle of their length, making three punctures (using the hypodermic syringe). The pain was sharp and smarting, and increased on removing the compress from over the pubes some three hours after; ordered evaporating lotions and support to the scrotum. Operated at 10 A.M. Saw him again at 10 P.M.; was surprised to find the amount of coagulation; one clot large as a hulled walnut, a little tender.

24th.—The clots firmer; no increase in size, but the walls of the spermatic vessels resisted being pressed together, and from this time they underwent rapid diminution, no blood circulating through them.

This patient went home on the 29th of June. I saw him in August. The spermatic vessels had so far disappeared and the remains of them were so cord-like in feel as to make it difficult to distinguish them from the vas deferens.

Remarks.—Out of thirty-five cases thus treated I have not found an undue amount of inflammation, yet the inflammation has always caused such organic changes in the serous lining that adhesion or absorption followed.

In all the cases the effects of the use of ergotin appeared remarkably mild, equally suitable to old age and youth; and the return of the parts to their natural condition seemed more speedy than after the use of iodine, port wine, or even the primary galvanic current, which latter I have used over twenty-two years.

It might be a question whether, in these examples, the cures were in reality complete, as some of the parties were seen so short a time after operation (some living at a distance); but I have no doubt on the subject, as out of many instances where I pursued a similar practice I have never had a patient return with the disease again upon him, and the worst of the above cases I know, from personal observation since, to be cured.

Case I. was somewhat peculiar; I termed it encysted hydrocele of the spermatic cord, under the impression that it was so. If such were the fact, it was, it would be observed, an instance of this form

of disease (comparatively a rare one) occurring after the successful performance of the radical operation for effusion into the tunica vaginalis. I thought possibly the collection of fluid had taken place in the upper part of that cavity where adhesions had not been produced; but my experience went against this view, for if adhesions in any case had been caused throughout almost the entire extent of the serous surfaces, the actions in any non-adherent part were so altered that the disease rarely, if ever, recurred. Besides, if this had been the state of affairs, in all probability the recent adhesions would have yielded in such a manner that the swelling would have increased in a downward direction, and occupied far less of the inguinal direction than it did in reality.

Case II. presented a variety, inasmuch as there was an irreducible hernia present as well as a hydrocele. The hernial sac was, in my opinion, filled with omentum, which had become so altered in shape and consistence, and possibly also adherent, as to be irreducible.

I would not have resorted to more than simple tapping, for the radical operation could not be discerned so free from danger as in an ordinary case. The inflammation might extend from one serous membrane to the other, and both being so contiguous the effects might be alarming. The patient, however, was about to proceed to parts of the world where he might not have the advantages of surgical advice; and even in the event of his being seen by some other surgeon, with the hydrocele perhaps much increased, there might be greater difficulties and dangers under such circumstances than were at present apparent. I accordingly used the injection stated, but not without having made sure there was no direct communication between the two sacs. Fortunately, there was no extension of the inflammation, and the case might be considered as simplified in character, there being only one disease instead of two, the remaining one being probably in that condition that it would never alter. In this instance the patient had complained of considerable pain in the abdomen immediately after the operation, which, under the circumstances, caused me more anxiety than common examples. My anxiety, however, was allayed by the fact that some persons feel great pain in the course of the spermatic cord after injection of iodine, etc., extending to the loins and even to the whole abdomen; and doubtless this was the case here, and not from any continuous action on the peritoneal surface.

For the last seven years I have had frequent opportunities of witnessing the effects upon animals of ergotin injected in the tunica vaginalis communis, in producing adhesion or absorption of the lost fluid in the sac. On examining the pig (the animal selected) after operation, in nearly every instance there was firm adhesion, and the sac was so altered anatomically as to defy the distinction from the tunica albuginea: the cases noted extended to fifty-six, including those in which I injected tincture of the perchloride of iron in the cord and spermatic vessels, to produce atrophy of the testes instead of immediate castration. The age of the animal was from

two to eighteen months. The large size of this animal, the active circulation of the blood through its spermatic vessels, and the facility presented by the number so easily obtained, have given me almost unlimited number in one year for experiment, as all the males are castrated as early as possible.

Case III. occurred in a person seventy-three years of age, a period of life at which it is seldom advisable to operate, on account of the danger of shock to the system; the patient should be content with occasional tapping; but here I acted otherwise, being induced to do so chiefly on account of the hale and comparatively robust condition of the parts affected and the mildness of this treatment. The treatment of this and the fourth case resulted in a rapid and, to present appearance, permanent cure.

Case IV., apparently so serious, is now following the laborious business of *tilling, ditching, hedging*, etc., and declares himself to be *as well as he ever was in years past*.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

SURGICAL CLINIC OF DR. T. J. MORTON, NOVEMBER 22.

Reported by J. J. KIRKBRIDE, M.D.

DR. MORTON presented to the class several specimens, illustrating a gunshot wound involving the knee-joint, the popliteal artery, vein, and nerve, and gave the following history of the case:

My friend R. H. Wevill, M.D., a prominent practitioner, residing in the lower section of the city, aged 45,* received a pistol-wound in the left knee, Nov. 17, 1874; the ball entered on the inner side of the knee, opposite the internal condyle, an inch below margin of the patella, passed through the popliteal space, then upward to the outer side of the thigh, and was found immediately under the skin on the outer part of the biceps muscle, and was extracted by Dr. Nebinger at 6 P.M. the same day. At 6.30 P.M. I saw the patient, and found him suffering intensely from pain in the limb, which was cold below the knee; very great swelling existed in and adjacent to the popliteal region and calf of the leg; there was no pulsation in either the anterior or posterior tibial arteries, and there was total loss of sensation on the outer side of the foot, with a general numbness of the entire leg; there was considerable shock, a quick pulse, a cold skin, and a blanched countenance. He had taken two grains of morphia, and had the knee leeches on his own responsibility. At 10 P.M. I had a consultation with Drs. Nebinger and J. H. Packard; we found marked heat in the leg, but no pulsations could

be felt; there was continuous shock; pulse 115; skin cold. A wound of the popliteal artery was diagnosed, with perhaps involvement of the vein and contusion or wound of the nerve.

It was decided to envelop the limb with cotton, to apply hot laudanum fomentations around the knee, to administer milk-punch and liquid nourishment, and to await reaction. We again met in consultation Nov. 18, at 12.30; pulsation was now found in the anterior tibial artery, with undue heat in the limb; marked pulsation also existed in the ham, with distinct aneurismal bruit.

The consultation decided that the ball had opened the artery, forming a false aneurism, and that an exploratory operation should be made; that after opening the popliteal space in a median line, should the artery and vein be found injured with any joint-complication, amputation should be performed, or to be guided by the circumstances.

After etherization, I made an incision in a median line five inches long; on reaching the cellular tissue, an immense mass of clotted blood was found, which extended down to the femur; the finger passed in found loose fragments of bone and evident involvement of the knee-joint; the deep tissues and blood-vessels were so extensively lacerated that it was determined to amputate the thigh, which was done by rectangular flaps; little or no blood was lost. The patient bore the operation well, and the stump was brought together with silver wire, dry dressings were applied, and a firm roller from the groin down.

Examination of the limb.—The popliteal region was found infiltrated with blood, which extended down below the soleus and gastrocnemius muscles in large quantities; small spiculæ of bone were found among the clots. The external popliteal nerve was severely bruised, having been brushed by the ball. The popliteal artery was opened, presenting a roughened oval wound, rather more than an eighth of an inch in diameter; the vein was wounded in two places, the ball making a wound of entrance and a wound of exit; both these openings were double the size of the wound in the artery. A small fragment of bone was found driven into the substance of the artery near the opening. The ball passed directly through the inner tuberosity of the inner condyle of the femur, from below upwards, producing a comminuted fracture, the wound of entrance being small, while the wound of exit showed much splintering. The interior of the joint presented the synovial membrane intensely congested, and there was marked increase of the synovial fluid.

Since the operation, the patient has been doing well.

HYPODERMIC USE OF QUININE (*New York Medical Journal*, November, 1874).—Dr. Alfred A. Woodhull reports three cases in which he has used, hypodermically, a solution of quinine of about six grains to the drachm.

The first was a case of quartan intermittent; the results were about the same as follow the oral administration. The only immediate local effect at each puncture was the death of the skin and its discoloration over a spot about a fourth of an inch in diameter. The second was a quotidian intermittent, which was cured. But in this case every injection was followed by the local death and sloughing of the tissue infiltrated, the sloughs being circular, and varying from three-fourths of an inch to an inch and a quarter in diameter. The patient was incapacitated from work for five weeks.

The third case was one of typhoid fever, in the early stages of which the injections were given. Fourteen of these were followed by local sloughs as in the preceding case, and were painful and annoying for weeks.

* Dr. Morton, on account of his legal connection with the case, has very properly refrained from giving any statement in regard to the circumstances of the shooting of Dr. Wevill. There are several versions of the affair afloat, and until the legal investigation is made it is impossible to arrive at the exact truth. The following narration is, however, probably substantially correct. Dr. Wevill received one or two notes from the husband of a lady whom he had previously attended, asking him to visit her professionally. He did so, and whilst at the house the lady asked him up-stairs to see some new furniture, or upon some other pretext. Directly after this the husband came into the room with a writing in one hand and a cocked pistol in the other, and demanded that the doctor should sign the paper, which was an acknowledgment of his having had criminal connection with his patient, threatening to shoot him if he refused. The doctor did refuse. An altercation ending in a struggle ensued, and the pistol was discharged. No one, so far as we know, believes that the charges against the doctor had any foundation in fact. His friends seem equally divided between the belief that the shooting was the result of an insane jealousy, and that it grew out of an atrocious attempt at blackmailing.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

SATURDAY, DECEMBER 5, 1874.

EDITORIAL.

HOSPITALISM.

A VERY noticeable feature of the papers upon hospitalism read at the late meeting of the American Health Association, and of the subsequent debate, was the singular unanimity in regard to the object to be attained and the singular diversity in the methods of reaching it. It is a universal therapeutic rule that when a large number of remedies are strenuously recommended by different authorities in any disease, no one of them is in any sense a specific, and most of them are about of equal value. We cannot help thinking that this rule holds good in the present instance, and that probably there is not much difference in the working value of the different plans; that the results depend more, far more, upon the *management* of the hospital than upon its mode of construction; that a good medical superintendent is of more consequence than any especially recommended system of ventilation; that in scrupulous cleanliness and an avoidance of overcrowding, and in the watchful care of one who is thoroughly trained for his work and has the brains to use such training, are to be found the requisites for success in hospital management. Beyond this, the problem seems to us largely as to the individual needs of the proposed hospital, and the comparative expense of the various plans.

As every case of sickness demands an individual study, so does every hospital problem. The amount of ground at the disposal of the institution, the

nature and situation of that ground, whether the institution is or is not to be used for clinical purposes, etc., may seem unimportant when compared with the question, What is best for the patients? Yet these secondary matters are really of very great importance; and, when it is evident that many plans are of about equal utility so far as concerns the welfare of the sufferers, such secondary considerations must be decisive.

In regard to the question of comparative expense, we have yet to see a fair estimate of the various plans made or even attempted. The first cost of a hospital is but a small part of the outlay. What folly, then, to make this the entire basis of comparison! The plan of a hospital undoubtedly does influence very greatly its running expenses, and a fair comparison between two rival plans must take this into consideration.

The great differences of opinion ought to teach medical writers humility, and all should remember the possible influence their words may have upon the benevolent. To denounce in unmeasured terms our present hospital systems is certainly unnecessary and injudicious; and, indeed, in the light of the results obtained by Mr. Callender in England, by Dr. Goodell in this city, and in the Pennsylvania Hospital, such language seems to us to partake of the nature of folly.

The Pennsylvania Hospital is old-fashioned in the extremest sense of the term. It has had its wards full of the worst surgical cases during many decades; and yet we doubt whether any private practice can show a better result than is there obtained. Until some one points out a fallacy in the statistics offered by Dr. William Hunt in his recent letter to the *Times*, we hope to hear fewer tirades against large and permanent hospitals. If surgeons in whose wards the evil results are obtained would once get the idea that perhaps their personal management of their cases and of their wards ought to bear the blame which they are so eager to lay upon "faulty construction," we should probably have fewer deaths inside and less complaints outside of hospitals.

In all astronomical problems the "personal equation" of the operator is always ascertained beforehand and taken into account. How much more important is the "personal equation" in surgical practice! Yet what medical statistics take notice of it? Comparative statistics, unless when the differences in them are very great, are a fraud and a delusion; and we doubt if any one will ever obtain a result much better than that of the surgeons of our old medical landmark.

LEADING ARTICLES.

THE TRANSMISSIBILITY OF TUBERCULOSIS.

I.

THERE is no question in modern pathology, human and comparative, fraught with greater interest and importance than this of the probable, nay, certain, transmission of tuberculosis from mankind to animals, and, possibly, from these to the human species. The solution of this problem is not only of urgent importance to sanitary science and the preventive medicine of the future, but so seriously concerns us individually of the present day as to demand our closest attention.

It becomes our imperative duty, then, to ascertain whether we are actually engrafting upon our children the fatal malady of tuberculosis by inadvertently administering to them milk derived from phthisical cows, as the experiments made by Klebs, Böllinger, and others lead us reluctantly to believe. It appears, also, further that we are all exposed to nearly the same danger of infection in eating the flesh of cattle, when, as not unfrequently is the case, it is loaded with pernicious tubercular matter.

The revival, in certain quarters, of the belief that tuberculosis is contagious, even in the human species, as Morgagni asserted more than a century ago, suggests the reflection whether we, as physicians and teachers, lay sufficient stress upon the great danger of allowing healthy people, especially young children, to associate with those who are consumptive.

We have yet, it is true, a great deal to learn with regard to the pathology and communicability of this disease; but there can be no hesitation in recognizing the importance of the results already achieved by careful experimentation and observation. Startling as the above assertions may appear, that milk and flesh, such important articles of our food, as well as mere cohabitation, may prove media for the conveyance of tuberculosis, yet nevertheless, in the presence of so many important facts, we must yield them our credence. In short, we fully concur with Chauveau, who says, "It now appears proved that the identity of tuberculosis with the other virulent diseases is so complete and so absolute that we must either recognize its virulency, or deny the existence of virulence altogether. There is no middle place in this dilemma."

And now for our facts. But first let us see how the authorities agree as to the histological identity of human tubercle with that occurring in the lower animals. A remarkable unanimity of opinion exists upon this point at the present time. Professor Reynal,* of the Alfort Veterinary School, stands almost alone in maintaining that the bovine and human tuberculosis are essentially different in their histological features. While admitting that the elements of the bovine tubercle are incontest-

ably identical with those of sarcomatous tumors, this writer, nevertheless, sees proper to separate it from the latter on account of the absence of nutritive vessels and the determinate volumes which can never be exceeded by the tubercular new growth. The majority of the authorities, however, appear to take the opposite view; of these, Prof. Schüppel,† who has made an almost exhaustive study of tubercle in general, and particularly that of the bovine species, has unquestionably fully established the absolute identity in structure and development of the cattle-disease with tubercle in man. Accepting, then, the fact as fully established that human and bovine tuberculosis are identical, the numerous and apparently authentic and exact observations—a few of which will be given later on—as to the extension and transmissibility of tuberculosis in the different species become somewhat startling; but the results of experiments undertaken by various authorities with the view of ascertaining whether the disease could be produced by inoculation with or the ingestion of tuberculous matter, are yet more so. As most of these experiments are no doubt already familiar to many of our readers, we shall do no more than summarize the conclusions drawn from them, excepting a few of the more recent ones, to which, perhaps, as yet, less prominence has been given.

So prevalent was the tradition of the inoculability of tuberculosis that even Morgagni abstained from making autopsies upon the phthisical, and Laennec alleged that he had acquired a tubercular ulceration upon his finger in this manner; yet, strange as it may seem, and despite this long-noted tradition, it was reserved for Villemin to establish, in 1865, by actual experimentation, the certain transmissibility of this affection by inoculation. The animals experimented upon were chiefly rodents,—rabbits and guinea-pigs,—and the material, tubercle from the human lung. The number of animals inoculated was large, and tuberculosis, more or less extensively developed, constantly resulted. No matter in what part of the body these inoculations were made, the tuberculization that followed was marked by the same serious characters in all, many of the creatures dying after a variable period, and others, falling into a state of marasmus, were killed. The lesions noted in them were chiefly found in the lungs, which were more or less infiltrated with tubercles; but other organs and textures were not exempted,—the spleen, liver, bronchial and mesenteric glands, etc., being also involved in many cases. Experiments were also made upon ruminants and carnivora (sheep, dog, and cat), but the results with these were generally negative; though a few of them so inoculated were found with the characteristic gray granulations and cheesy deposits in the viscera. Villemin also determined by further experiments that the tuberculous matter of animals, especially that of the bovine species, could give rise to tuberculization. From these experiments he concluded that bovine

† "Ueber die Identität der Tuberculose mit der Perlsucht," Virchow's Archiv, Bd. 56, S. 38, 1872.

phthisis is identical with that of man. The next step was to ascertain whether the tubercular matter thus produced by inoculation was also capable, like that which arises spontaneously, of being transmitted; or, in other words, whether its virulence was retained beyond the primary transmission. The second generation of tubercular matter was found to have retained all its morbid activity, causing intense tuberculization in an equally short period. Villemin concluded from his experiments that phthisis in mankind was the result of a specific or virulent agent introduced into the organism.

Since the first report made by Villemin, numerous other experimenters have tested the validity of his statements, so that the successful inoculation of the lower animals with tubercular matter has ceased to be a novelty. Among these experimenters we find the names of Colin, Vulpian, Lebert, Cohnheim, Frankel,* Papillon, Nicol, Roustan, Laveran, Empix, Waldenberg, Wyss, Wilson Fox,† and Burdon-Sanderson; of these, the famous papers of the latter,‡ so extensively quoted by English writers, are probably the best known to American readers. All these experimenters succeeded in developing in rabbits and guinea-pigs a disease analogous to tuberculosis by inoculating them with tubercular products (gray granulations, caseous matter, and the sputa of phthisical subjects). It is evident "that the certain result of inoculation of tuberculous matter, of whatever kind, is to produce granulations in the lungs and other internal organs; that these granulations are anatomically identical with gray tubercle, that they become yellow or opaque, and eventually break down into a soft cheesy material. It is further admitted on all hands that the process is, so to speak, a self-destructive one; that in the act of inoculation a new element is introduced into the inoculated animal at the point of insertion, from which it is disseminated to all parts of the body through the lymphatics and arterial circulation."§ This latter statement is not invalidated in the least by the fact that the same effect may be brought about by the use of non-tubercular matter or the application of irritating setons, or other substances acting chiefly as mechanical irritants.

The results of these experiments seemed, it is true, to lead to views antagonistic to the idea of the specific nature and virulence of artificial tuberculosis; but they have been explained by stating that caseous deposits were first formed at the point of inoculation, or where the seton had been introduced, next in the neighboring lymphatic glands, and that it was the caseous matter thus formed which gave rise to the production of tubercles throughout the economy. This explanation is, moreover, entirely conformable to Niemeyer's theory of the development of tuberculosis in man,—a caseous deposit in any portion of the body (lungs, glands, articulations, bones, etc.) being, above all other

things, according to this authority, a predisposing cause to tuberculosis; and if the lungs are so frequently tuberculous, this is because in them oftener than anywhere else this caseous matter is formed. He further pointed out that the infection of the blood does not always arise through a cheesy deposit, as alleged by Bühl, since cases of acute tuberculosis occur in man in which no trace of such a deposit exists.¶ He, with others, believed in a gradual generalization of tubercle through the medium of the lymphatics, while Lebert** thought that capillary embolism was always an important factor in the artificially-engendered tubercle. Bühl's theory seems, however, to have been generally accepted in so far as experimental tuberculosis in animals is concerned.

Villemin†† performed a further series of experiments to meet the objections brought against his views, and presents, in an address delivered before the Imperial Academy of Medicine in 1868, some very telling and convincing arguments with regard to the production of tuberculosis by inoculation. In these experiments he sought to realize, in principle, the conditions of a real inoculation,—to wit, a very small wound and an inconsiderable quantity of inoculable matter. Although these conditions were never departed from, tuberculizations extremely variable in their intensity and generalization were obtained; every degree being noted, from a few isolated granulations to those startling generalizations in which every viscus was crammed with the tubercular product, a manifest proof that *the intensity of tuberculization is completely independent of the quantity of matter inoculated*. Observing that the alterations in the lymphatic vessels and glands were far from constant, they often remaining unaltered, and the local tuberculization at the point inoculated was often quite rudimentary, while the viscera of the animal were richly tuberculosed, therefore, says Villemin, *the number and extent of the internal lesions have no relation to the local lesions at the seat of puncture*.

The transmission of tubercle has been likened to a process of grafting; "but how can such a process explain the myriads of tubercular granules which stud the parenchymatous and serous organs?" asks Villemin. "Grafted tissues continue to live and develop at the places where they are deposited, but they are not reproduced elsewhere in the organism. This theory, at the most, could only explain the development of tubercle at the seat of puncture; and even then the inoculated tuberculous matter, to do this, must be endowed with a very active vitality. But the softened matter in the centre of a tubercle does not even contain any distinct elements; we inoculate only with a *détritus*. How can grafting explain the successful inoculation with sputa,—*sputa which has dried for twenty days*, as has occurred in our experiments? Does not all this prove that the inoculated matter acts by virtue of a principle inde-

pendent of the histological elements entering into its composition?"

The *quasi*-tubercles induced in man and animals by various parasites, the microscopic appearances of which so closely resemble those of tuberculosis, are discussed by Villemin, as well as the results of injections of mercury, tallow, dust, and irritant substances of various kinds, even pus, into the bronchia and veins, and the great difference between them and true tuberculosis pointed out. To confound the former with the latter would be as great an error as to identify the pustules produced by tartarized antimony with those of variola.

Demet, Paraskev, and Zallonis, of Syra, Greece, not content with their success in transmitting this disease to rabbits by inoculation with the sputa and blood from a man affected with phthisis, performed the unprecedented and not-to-be-repeated experiment of inoculating a human patient whose history afforded no suspicion of a tuberculous taint, and whose lungs were perfectly healthy, but who was suffering from gangrene of the big toe of the left foot, due to femoral embolism. Amputation of the limb would not be submitted to, and, as a fatal termination was inevitable, a quantity of sputa from a man who had abscesses in his lungs was inoculated in the upper part of the left thigh. Three weeks afterwards, auscultation revealed very slightly increased respiratory murmur at the summit of the right lung, and somewhat prolonged expiration in the subclavicular region. Thirty-eight days after the inoculation, the man died from gangrene; and, on examination of the body, it was found that the upper right lobe had seventeen tubercles in the first stage of development, of a gray color, and very hard. Two granulations each were found in the left apex and upon the surface of the liver. From this unusual experiment, as states Fleming,* from whose paper we have freely abstracted throughout, "it is evident that tubercle is inoculable in man himself, for it is scarcely possible that this patient, who was fifty-five years of age, could have had his organs infiltrated with as many as twenty tubercles in the first stage of development only. Had they been naturally developed, they must have multiplied and passed through their regular evolution, especially in an individual predisposed to phthisis. Their limited number, stage, and size, afford a direct relation to the brief interval separating inoculation from the decease of the patient."

CORRESPONDENCE.

IS FRACTURE OF THE PATELLA AMENABLE TO TREATMENT?

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—I notice in the last issue of the *Medical and Surgical Reporter* an abstract in reference to the treatment of fracture of the patella at the Hôpital

Lariboisière, Paris, in which the practice of that institution is stated to be that "It does away with all apparatus, much to the comfort of the patient. The plan is simply to place the affected limb on an inclined plane, and to keep it steady by means of a few turns of a roller, without striving to bring the fragments together; a measure perfectly useless, as, whatever is done, the surgeon can rarely expect anything more than a fibrous union, which, after all, does not interfere with locomotion. What this plan studies to avoid is stiffness of the knee-joint, which so frequently follows prolonged immobility of the limb."

I am particularly impressed with the article, perhaps on account of the fact that some of my own remarks on fracture of the patella at a clinic of the Pennsylvania Hospital, intelligently reported by Dr. J. B. Roberts, are published in the same number of that journal, and because my practice and teaching are so diametrically opposite to those of the Hôpital Lariboisière. The article is, in my opinion, calculated to do harm by its teaching of such practice, endorsed by the influential authority of a prominent European hospital.

I have seen three instances in which fracture of the patella was left without further treatment than a state of rest to the limb; no attempt being made to secure mechanically the coaptation of the fragments. In one case the fracture was associated with other injuries, almost necessarily of a fatal character, but the patient survived for nearly three months. In another instance the fracture was complicated with severe injuries of the limb, which were attended with such great swelling that the fracture was not recognized until after the lapse of more than two months. In the third case the fracture was treated as a simple sprain, with rest alone, by a "homœopathic surgeon," and the patient came ultimately under my care on account of permanent disability of the limb, due to a separation of the fragments of not less than five inches.

In each of these cases the separation of the fragments remained far greater than I have ever seen it as the result of ordinary treatment in which approximation is effected as thoroughly as is usually practicable. These opportunities of observing the natural history of fracture of the patella do not incline me to favor such masterly inactivity in its treatment as is practised in the French hospital alluded to.

As to stiffness of the knee-joint following the mechanical treatment of fracture of the patella, I may merely remark that the resulting stiffness is due to the synovitis and other inflammation of the surroundings of the fracture, rather than to "prolonged immobility," which is not during a longer period nor more thorough than is necessitated in ordinary cases of fracture of the femur or of the tibia. In regard to "a fibrous union not interfering with locomotion," I know from practical observation that a *long* fibrous union, as is likely to result from such want of treatment as is the custom at Lariboisière, does interfere with normal locomotion.

While impressing the facts that much of the separation of the fragments in fracture of the patella is due to the

* George Fleming, "The Transmissibility of Tuberculosis," British and Foreign Medico-Chirurgical Review, No. cviii., October, 1874.

swelling of arthritis and bursal distention, and that coaptation cannot be effected until these conditions are subdued, I always teach methods of mechanically approximating the fragments as soon as may be practicable. With efficient mechanical treatment I have seen a number of cases in which, if true synostosis was not effected, the fibrous union was so short that no separation was appreciable.

After some experience with various mechanical contrivances for the treatment of fracture of the patella, I am convinced that the best results, with the most comfort to the patient, can be produced by the simple use of long strips of adhesive plaster and roller-bandages, and with either the limb elevated or the trunk kept raised, so as to flex that portion of the quadriceps muscle which has a pelvic origin. The strip holding down the upper fragment should be long enough to reach spirally down the leg, continuing even to the sole of the foot. In order to render the dressing very secure, several strips of adhesive plaster may be superimposed, so as to give strength and solidity. Strips passing in a contrary direction readily maintain the lower fragment in position, as there is no muscular influence tending to its displacement; and a roller-bandage, enveloping the entire limb, completes the dressing.

During some recent observation in European hospitals, including the Hôpital Lariboisière, I found no practice in the general treatment of fractures, to which we are in this country not accustomed, that is worthy of our imitation. On the contrary, the treatment of fractures in most European hospitals is often careless, unmechanical, and unphysiological. The most favorable exceptions to this condemnation I saw in one or two hospitals in London. From the general practice of the French surgeons in the treatment of fractures we have surely nothing to imitate. I saw, however, in some European hospitals a fair and creditable attempt at the introduction of what they term the "American methods" of fracture-treatment, particularly in the treatment of fracture of the femur.

I trust that the expectant plan of treating fracture of the patella will not be copied in this country; but if there be those whose fondness for and reliance on French authority must incline them to imitate, I would suggest to them the probability of involvement in litigation for malpractice, in suits in which their surgical brethren might not be able to endorse their practice.

R. J. LEVIS, M.D.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A CONVERSATIONAL meeting was held October 14, 1874, at 8 o'clock P.M.

PRESIDENT, Dr. WASHINGTON L. ATLEE, in the chair. Dr. O'HARA asked if any gentleman present could give him any instruction in the method of strapping the

chest in incipient phthisis. Surgeon McCrea, of the Belfast Dispensary, in the *Lancet* for July 18, 1874, recommends a process of strapping with emplastrum roborans. He states that there is a marked diminution of cough, cessation of pain, relief of dyspnoea, and a reduction of temperature by the repose thus given to the chest-walls. The patient at once expresses a feeling of great personal comfort. By repeated applications, once a fortnight, he would hope for brilliant results. When it became loose, the recurrence of the cough admonished the patient and his friends of the necessity of its reapplication. He has seen no account of its trial on this side of the water.

Dr. WELCH stated that this subject would probably be brought before the Society during the winter in the form of a paper.

Dr. H. C. WOOD called attention to a paper in the current number of the *British and Foreign Medico-Chirurgical Review*, which seemed to him to prove the contagiousness of phthisis, and remarked especially upon the fact, seemingly proven, that a stall will become affected so that healthy cattle placed therein will contract the disease. The bearing of this upon consumption-hospitals is very obvious. The moral and hygienic objections to such institutions are overwhelming, and should cause them to be entirely abandoned.

Dr. LEE said that observations which had been made in the early history of the efforts to treat chronic affections by means of remedial exercises and localized movements had an interest in this connection from a negative point of view. As is well known, physical exercise is one of the most powerful agents for improving nutrition. We find it so in health, and it is not less so in ill health. Now, phthisis is, to a great extent, a disease of impaired nutrition. Hence it was concluded by enthusiastic investigators of this new method of treatment that movement would be just the thing for it. They began vigorously with such exercises as would tend to develop the chest and call into play the muscles of respiration. But they soon found themselves obliged to desist. Their patients grew manifestly and rapidly worse instead of better. They then adopted the alternative of confining their efforts to the muscles of the lower extremities; and by exercising them cautiously so as not to quicken the respiration, they found that they were able to avoid any such disastrous results as were at first observed, and in some instances to produce decided benefit. If, then, increased action of the thoracic muscles is injurious in this disease, it is a fair inference that enforced rest of these muscles, and hence, to some extent, of the subjacent lung-tissue, may be beneficial.

Dr. ATKINSON thought this idea militated against the plan of "roughing it," so often suggested and urged upon consumptives. He was sure he had seen marked benefit from this plan in repeated instances, and mentioned a case which he had encountered in California, where horseback-riding the whole distance from New York City had acted in a highly beneficial manner.

Dr. HAMILTON said the proposed new method for the cure or retarding the progress of phthisis was, as intimated by Dr. Atkinson, in singular contrast with the practice of physicians now or in earlier times. The late Dr. Joseph Parrish used to narrate in his lectures the history of a number of most striking cases illustrative of the great advantages of much out-door exercise in this disease. So, also, Dr. Benjamin H. Coates, when physician to the Pennsylvania Hospital, made it a point to recommend such of the consumptives as were quite able to take exercise to leave the wards of the hospital, assured that, in so doing, they would protract the issue of the malady. The propriety of this practice is confirmed by the experience of practitioners generally.

Dr. LEE said, in reply, that probably every member present could recall precisely similar cases to those which had been detailed, and that no one would be readier than himself to prescribe just this remedy in the earlier stages of phthisis. But "roughing it," in such cases, meant simply getting an abundance of fresh air; and fresh air, as we all agree, is the panacea in such affections. He believed, however, that just in proportion as our patients, while availing themselves of this invaluable remedy, avoid violent exercise of the muscles of the upper extremities, will they profit by it. In regard to the use of these muscles in horseback-exercise, which has often been found beneficial in phthisis, he would say that, in riding, the muscles which are brought strongly into play are the erector muscles of the spine and lateral muscles of the abdomen, which assist in preserving the equilibrium of the trunk, and the abductors of the thigh, with which the saddle is grasped. But one may ride all day without touching the reins or bringing the arms into powerful action.

Dr. O. H. ALLIS read a paper on Anæsthetics. (See p. 145.)

Dr. H. C. WOOD stated that he had been exceedingly interested in the very practical paper of Dr. Allis, but that he thought the difference of energy in the two agents was not the sole cause of the different mortalities following their use. The English Chloroform Committee years ago established the fact that in the animal, during chloroformization, the blood-force steadily falls from the very commencement, whilst during the anæsthesia of ether the arterial pressure rises and is maintained for many hours, only falling when the respiration is sensibly interfered with.

The same facts the doctor believed to be true in regard to man. When chloroform is inhaled, the pulse can often be felt to grow weaker, whilst after a few drafts at the ether-sponge the wave becomes fuller and stronger. For these reasons, whilst ether may be safely administered to a patient when standing, chloroform should never be given except to a person lying down. Ether stimulates the heart; chloroform paralyzes it. Ether kills through the respiration, by asphyxia; chloroform very often destroys through the circulation, by syncope. Upon these facts, rather than upon the comparative energy of the two agents, Dr. Wood conceives, rests the difference in the danger that attends their use.

Dr. Allis, being asked by Dr. Wood for the cause of death from chloroform, said that he had no theory to offer for its fatal action, other than the theories already familiar to the profession; that he had, however, watched and carefully studied the effects of the two anæsthetics upon himself, and a similar succession of phenomena was produced in every instance; that he was quite certain in his own mind that to a *greater anæsthetic energy*, rather than to any difference in kind, might be attributed the greater frequency of death.

Dr. W. GOODELL said that the paper of the evening was of great practical value, and that he, for one, felt himself under deep obligations to Dr. Allis for bringing up the subject of anæsthetics before the Society. He himself generally preferred ether, as being a more trustworthy agent, but he was now sensible of having made the very mistakes in its administration which had been so clearly pointed out in the paper. In future he should strive to avoid them by carrying out the mode of administration so ably advocated by Dr. Allis. In regard to the depressant effect of chloroform on the circulation, he was entirely in accord with Dr. Wood. Apart from crucial experiments, the method of resuscitating cases of threatened death—viz., by lowering the head and raising the body—so vividly described by Dr. Sims before the British Medical Association, goes to sustain this view. So also does an able paper

of M. Campbell, of Paris, in which he contends that the immunity with which parturient women inhale chloroform is owing to an antagonism between the effects of labor and the effects of this anæsthetic. Chloroform induces anæmia of the brain, but the throes of labor congest the brain, and, therefore, act as an antidote.

Dr. ATLEE desired to make some remarks on the position assumed by the lecturer with regard to the use of a combination of chloroform and sulphuric ether. For over twenty years he has been in the habit of administering it, and has never seen any bad results arising from its employment. He uses it in the proportion of two parts of ether to one of chloroform; and introduced this formula to the profession many years ago. It is not a mere mixture. A chemical combination occurs between the two fluids, and heat results in consequence of a condensation in the union of the two fluids, the same as when sulphuric acid and water are united. If it were a mixture, one would separate from the other; but the combination is permanent, as he has kept it unaltered for months. Dr. Atlee believes that the combined liquids vaporize simultaneously and in combination, and not independently and separately as is supposed. Although the boiling-point of ether is about half that of chloroform, and about one-third below that of water, yet the specific gravity of its vapor is about five times greater than that of water.

Dr. Atlee has frequently kept a patient under the influence of his anæsthetic an hour with one and a half ounces of the liquid. His method is to use a starched napkin, eighteen inches by twenty-four, folded lengthwise into three folds, embracing a *Ledger* newspaper, and then rolled into a cone and securely pinned. A few drops only of the liquid are dropped on the inner side of the cone, and the latter placed over the mouth and nose. No sponge is placed in the cone. Solid food is not allowed for twelve or sixteen hours before, and nothing for three hours previous to the administration of the anæsthetic. The patient, in a recumbent posture, is brought slowly under its influence, and the cone is removed on the least indication of heavy breathing. As he has used this combination between one and two thousand times without unpleasant symptoms, it is a matter of demonstration. He should be very sorry to see the use of chloroform forbidden by law. With regard to ether, Dr. Atlee stated that the lecturer had the day before yesterday administered it, by means of his apparatus, to a patient of his, on whom he had performed ovariectomy. He had never seen ether employed with greater pleasure and with better results. There was one effect, however, which, if constant, would render it inadmissible in ovariectomy. The muscles of the abdomen were not sufficiently controlled, and the intestines were forced out, so as greatly to impede the operation. The rigid muscles, after the removal of the tumor, had to be drawn aside by the hands of an assistant before the intestines could be replaced. The operation lasted forty-five minutes, and six ounces of ether were used. Dr. Atlee had used the bichloride of methylene on the recommendation of F. Spencer Wells, but found no advantages possessed by it over ether or chloroform.

Dr. Allis, in reply to Dr. Atlee, said that no one could witness the care with which Dr. Atlee prepared a patient for an operation, and not feel sure that any anæsthetic he would use would prove safe. He said that he was aware that the mixture of the two agents would remain unchanged while in a fluid condition; but the point of still greater moment was their behavior in the gaseous state. The fact that 96° Fahr. is the boiling-point of ether, while 142° Fahr. is the boiling-point of chloroform, must render the vapor given off from the mixture at an ordinary temperature an exceedingly changeable

one; and upon this condition alone he based his reasons for saying that the mixture was a dangerous one.

Dr. LEE said that he had used Dr. Atlee's mixture for many years without knowing to whom he was indebted for it. He had noticed this fact in regard to its preparation, which might have some bearing on the question of its being a true chemical combination: When the two fluids were poured together by the apothecary in a clean vial, the mixture very often presented a milky appearance, which appeared to him to indicate a failure to unite. He was then in the habit of requesting the apothecary to add a small quantity of pure alcohol to the mixture, say in the proportion of a drachm to three ounces, when the milkiess at once disappeared. In regard to Dr. Atlee's criticism on the lecturer's condemnation of this mixture, he had understood the lecturer to animadvert especially upon its reckless use by dentists while their patients were in the sitting posture. In this view of the question he thought too strong language could not be used, and he was sure that Dr. Atlee would be the last to wish to give the weight of his name to the impression that this combination was free from danger when used under such circumstances.

In reply, Dr. Atlee said that if pure concentrated or washed sulphuric ether is used, there will be no milkiess or cloudiness on mixing it with chloroform. Whenever the minute globules of chloroform can be seen floating through the ether on shaking them together, there is some fault with the ether, and a mixture, instead of chemical union, is the result.

Dr. O'HARA, in connection with the remarks of Dr. Atlee, who said he would not forego the use of chloric ether and chloroform unless compelled to do so, remarked that the moral responsibility of using chloroform and ether was very great. He thought the legal responsibility had already been fastened on us in view of the recent verdict of two coroners' juries in Boston, who seemed to be backed by the medical profession there; that medical men ought to be held to a criminal responsibility who used chloroform, which, in a certain number of cases, was death; whereas ether was considered to be harmless. He would also suggest, in reference to the danger in the use of chloroform, that some might use it with immunity. He had seen one person, who had been drinking freely, inhale and drink half a pound without inducing sleep. He must have been saturated with chloroform, as it was present in his vomit during the whole of the next day.

Dr. HAY is familiar with Dr. Atlee's mixture. He has used it for a long time, and has been present at many operations performed by Dr. Atlee for ovariectomy, when this mixture was given. Its use was followed by uniformly good results; it did its work well, and the patients recovered from its effects without an unfavorable symptom occurring.

In a recent case, in administering the mixture to a boy not quite six years of age, for the removal of an orbital tumor, it induced collapse three times, and he was obliged to discontinue its use and finish the operation with the patient under ether. In this case (the operation having been performed in a country town) there may possibly have been some fault or error on the part of the assistant in administering the mixture; but, at all events, the result was as stated. The operation was a painful one, the tumor being a large one, involving the removal of the eyeball and an extensive surface of periosteum, to which the tumor was attached. The time consumed in operating and resuscitating the patient was nearly two hours. The little patient made a rapid recovery, and is now well.

Dr. Allis being appealed to by Dr. O'Hara to explain why chloroform taken into the stomach was not so likely to prove fatal, said, "In the lungs we have fourteen hundred square feet of pulmonary mucous surface,

and over this entire surface the blood is spread out to favor rapid oxygenation. To this extensive surface the vapor of chloroform comes; while in the stomach, the chloroform in a fluid and gaseous state comes in contact with a comparatively small area."

Dr. KEYSER remarked that in 1865 he had the pleasure of being present at one of Dr. Atlee's operations, and then learned the doctor's mixture of chloroform and ether, which he (Keyser) continued to use for about four years, when, from having nearly lost three cases by it,—one a boy of ten years, on whom the operation for strabismus was made, another a boy of thirteen years, on whom an iridectomy was performed, and the other a man of thirty-three years, where the eyeball was enucleated,—the mixture was given up, and pure ether used since. He also mentioned that when he was assisting in the clinic of Prof. Von Langenbeck, in Berlin, in 1864, a somewhat similar apparatus to Dr. Allis's was used for chloroform. A single thickness of flannel was stretched across a wire frame, and the chloroform dropped on from a dropping-bottle.

Even ether has given him some trouble and worry. In one of his cases, lately, at the Wills Eye Hospital, a man some thirty years of age, after he was half under the influence, the breathing and pulse suddenly stopped, and it was with difficulty that the patient was resuscitated, after which the least particle of ether would cause a recurrence of the bad symptoms. His heart and lungs were found perfectly sound.

Prof. MCINTYRE, of Lafayette College, being present, was called upon for his opinion as to the chemical union between chloroform and ether. He said he would not be able to decide that question without experiment.

Dr. KEYSER said he had nearly lost three cases by the use of Dr. Atlee's mixture. He had been an assistant to Prof. Langenbeck, where a similar apparatus to the one described had been used.

Dr. DRYSDALE remarked that ether itself was not exempt from danger, as he himself had recently nearly lost a case from its use.

GLEANINGS FROM OUR EXCHANGES.

EXTIRPATION OF THE SCAPULA (*The London Medical Record*, October 21, 1874).—Dr. R. Schneider reports a case in which the left scapula was extirpated on account of a sarcomatous tumor. The first incision was made along the base of the scapula; the second was commenced at the acromion and carried horizontally along the upper margin of the tumor to the commencement of the first incision. A flap was thus formed, the free apex of which corresponded to the upper and inner angle of the scapula. The portion of tumor which projected beyond the upper margin of the bone was then exposed. The muscles attached to the inner and outer margins of the scapula were next divided. As the acromion, the neck of the scapula, and the acromial part of the clavicle had become involved in the tumor, it was found necessary both to open the shoulder-joint and to remove a portion of the clavicle. The deltoid muscle was cut through at its upper part, and the clavicle exposed and divided at an apparently healthy part. The articular capsule was now exposed, and the long tendon of the biceps muscles, and the tendons of the muscles inserted into the great and small tuberosities, were cut through. The articular capsule was then completely separated from the margin of the glenoid cavity. The axillary portion of the tumor was dissected out with great care, in order to avoid wounding any of the large vessels of this region. The tendons of the muscles attached to the coracoid process having next been dissected, the separation of

the tumor from the side of the thorax was easily affected. The supraspinatus, infraspinatus, and subscapularis muscles were wholly removed. During the operation, the subclavian artery was compressed against the first rib. A spray of carbolic-acid solution was played upon the wound during the operation. The vessels were closed by carbolized catgut, and the dressings were strictly according to Lister's plan. The operation lasted for little more than half an hour, and the hemorrhage was very slight; consequently there was no subsequent collapse.

The patient did well after the operation, and six weeks later was regarded as cured,—with a moderate amount of motion remaining in the left arm. Subsequently, however, the disease returned in the left shoulder near the cicatrix, and finally resulted in his death.

This is the nineteenth reported case of excision of the scapula with preservation of the upper limb. It was removed in two cases on account of caries, once on account of some obscure tumor, three times on account of enchondroma, once on account of an osteofibroid growth, and in thirteen cases on account of sarcoma or carcinoma. Of the nineteen subjects of these operations, one only died from the immediate effects. Two patients died from pyæmia, and one in consequence of bronchitis.

POST-PARTUM HEMORRHAGE—INJECTION OF PERCHLORIDE OF IRON—TRANSFUSION—RECOVERY (*The Lancet*, October 24, 1874).—Dr. Edward Henderson reports a case of post-partum hemorrhage occurring in a lady who was rendered anæmic by prolonged lactation, and who had previously had two severe floodings.

After the delivery of the child and the detachment of the placenta, the uterus refused to contract in response to friction, continuous pressure, etc., and a large quantity of blood was lost. After some little delay, iced water was freely injected into the cavity of the uterus, into which a piece of ice was also pushed, and the vagina was filled with ice. Partly by this, and partly by well-sustained compression, the bleeding was at last arrested, and the uterus, regaining a portion of its lost force, contracted fairly. Brandy and champagne were from time to time administered to the patient. At the expiration of two hours and a half, however, the bleeding recommenced; oozing went on rapidly; her surface and extremities became cold and blanched, her breathing sighing and interrupted, her pulse feeble and intermitting. Twelve ounces of a solution of perchloride of iron were at once injected, with the effect of immediately and finally checking the hemorrhage.

Soup prepared from raw meat by the addition of hydrochloric acid and water was given, together with stimulants, but the patient's condition grew more and more alarming. Her breathing was labored and irregular; her voice a mere whisper; her pulse 130, very feeble and intermitting. She said she was dying.

A saline solution containing about two drachms of pure alcohol was then injected into a vein by means of an apparatus acting on the gravitation principle. The change in the patient's condition which followed the operation was no less rapid than wonderful, the marked improvement in pulse, breathing, and general appearance making the prognosis much more favorable. Two hours later, however, all the bad symptoms returned, and her state was, if possible, worse than before. Twelve ounces of blood were then taken from her husband, were strained and defibrinated, and were injected through the same orifice by the same apparatus. The result was favorable beyond the most sanguine anticipations. The pulse once more filled and steadied, the breathing became full and regular, and by slow degrees warmth returned to the extremities. This improvement was permanent; the reactionary fever,

though marked, was moderate, and the patient completely recovered, with no untoward symptoms.

REST IN THE TREATMENT OF CHOREA (*The Chicago Journal of Nervous and Mental Disease*).—Dr. Ransom Dexter reports the case of a girl, æt. 13, whose health was impaired by hard study at school, and who finally became choreic. The treatment at first adopted consisted in the administration of extract of valerian and cimicifuga twice a day, the elixir of pepsin, bismuth, and strychnia before each meal, and bromide of potassium and cannabis indica at bedtime. In a few days she grew worse, and some malarial periodicity was noticed. It was then decided to try cautiously small doses of quinine and iron, but when only four grains of the former had been administered the following symptoms ensued: hemiplegia of the left side, dilatation of the pupils of both eyes, some choreic movements during sleep, increasing so much when awake that the patient was unable to sit up, but had to be held down on the bed or lounge. In reviewing the case, which had then become very serious from the general failure of the vital powers, Dr. Dexter arrived at the following conclusions:

1. That all the sensorial ganglia, or the centres for the nerves of the separate senses, were more or less affected; and that the sensori-motor centres were the special seat of the disease.
2. That the pathological condition could not be other than an asthenic irritation of the sensori-motor organs.
3. That these organs must have physiological and therapeutical rest.

Carrying out these ideas, he ordered the patient to be kept in a darkened room; to lie as still as possible upon a lounge; to be waited upon only by her parents, who were to maintain the strictest quietude; and to be positively silent herself. In addition, the valerian, cannabis indica, and bromide were continued, with an occasional cathartic to act as a revulsive. In eight hours a noticeable improvement had ensued, and in twenty-four hours had become very decided. In six days all choreic movements had disappeared.

THE VENOM OF THE SCORPION (*The London Medical Record*, October 21, 1874).—M. Jousset de Bellesme records, at some length, researches on the venom of the scorpion, and gives the following description of its situation and the mode of its ejection:

The poison-apparatus of the scorpion is lodged within the sixth and last caudal segment [probably the homologue of the mesial element, or "telson," of the last segment of the tail of a macrourous crustacean, e.g., a lobster, or crawfish.], which is of a rounded flask-like shape, and terminates in a horny blackish dart, recurved and very sharp. Within the ampulla are contained two little glandular sacs, communicating by a common duct, which extends into the dart to terminate near its point by two longitudinal slits, which are somewhat difficult to see. It is through these that the venom is injected, by the aid of the contraction of muscular fibres, which invest the glandular sacculles. In its natural attitude the tail of the scorpion describes a curve; but when the animal imagines itself to be completely sheltered against all dangers, it rests on one side or on the other, upon the ground. It is by a sudden extension of the tail that the dart, after being first brandished over the head of the scorpion, is launched against the body of the victim; and, however small be the prey, it is never brought to the mouth until it has been pierced by the sting. This is a measure of precaution; and that it is not an inherited instinct, but is probably acquired by bitter experience, the following instance will show. M. de Bellesme gave one day to a captive scorpion, which he had hitherto been feeding upon flies, a spider of the size of a pea.

The scorpion, having seized its prey with its chelæ, stung it *en règle*, but, probably owing to some flow of blood, the poison took no effect. The spider, *sicut est mos*, feigned death, and as the scorpion, deceived by this *ruse*, was about to transfer its prey to its mouth, the spider suddenly buried its "mandibles" in the base of one of the chelæ of the scorpion. The latter stung its victim anew, and this time with effect, but had scarce time to enjoy its victory before it began to show signs of discomfort, and was afterwards seized with tetanic spasms, from which it did not recover till the following day, when it ate a fly with good appetite. The scorpion always attempts to sting its prey in the thorax, death taking place much more rapidly when this site is luckily hit upon, the rapidity of its access being in the inverse ratio to the size of the victim.

MISCELLANY.

ORIGIN OF THE TRANSFUSION OF BLOOD.—The following paragraph is taken from Villare's "Life of Savonarola," and is perhaps the earliest recorded case of the operation of transfusion :

"The vital powers of Innocent VIII. rapidly gave way ; he had for some time fallen into a kind of somnolency, which was sometimes so profound that the whole court believed him to be dead. All means to awaken the exhausted vitality had been resorted to in vain, when a Jew doctor proposed to try to do so by the transfusion, by a new instrument, of the blood of a young person,—an experiment that had hitherto only been made on animals. Accordingly, the blood of the decrepit old pontiff was passed into the veins of a youth, whose blood was transferred into those of the old man. The experiment was tried three times, and at the cost of the lives of three boys, probably from air getting into their veins, but without any effect to save that of the Pope. He expired on the 25th of April, 1492, and without loss of time they set about the election of his successor."

DEATH FROM SMOKING.—The case is reported in France of a young man who perished in attempting to smoke twelve cigars for a wager. At the eighth cigar he began to feel uncomfortable, at the ninth he had chills and dizziness, which became more severe with the tenth. He still refused to stop smoking, but consented to go home with two of his friends. He was then attacked with vomiting and pain in the abdomen, and, in spite of professional assistance, he died in the night. It should be stated that the heart was hypertrophied.—*Boston Medical and Surgical Journal*.

THE CARRIER PIGEON.—The travelling pigeon never feeds. If the distance be long, it flies on without stopping to take nutriment, and at last arrives thin, exhausted, almost dying. If corn be presented to it, it refuses, contenting itself with drinking a little water and then sleeping. Two hours later, it begins to eat with great moderation, and sleeps again immediately afterwards. If its flight has been very prolonged, the pigeon will proceed in this manner for forty-eight hours before recovering its normal mode of feeding.—*L'Union Médicale ; Medical Times and Gazette*.

NOTES AND QUERIES.

3729 LOCUST STREET, WEST PHILADELPHIA.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

MR. EDITOR,—It is an old saw, that "one must go away from home to learn the news." I translate from the Portuguese the following article found in the *Carreto Paulistano*, which speaks for itself:

"SERVICE TO HUMANITY.—Two patients, one with stone in the bladder and the other with one in the kidney, who are in a hospital in Philadelphia, are being submitted to treatment by distilled water. Distilled water, according to the general belief of men of science, has a great solvent power.

"Dr. Moore (?), before proceeding to the operation of lithotomy upon the patient with stone in the bladder, ordered about half a pint of cold distilled water to be given to him an hour and a half before meals. The first effects of the experiment promising good results, Dr. Moore applied the same treatment to the other patient.

"Both of them expelled much very fine sand, and it was judged the concretions which affected them were being dissolved, because their pains had very much diminished. If Dr. Moore should obtain the results desired, he will do a great service to humanity. The treatment is simple, but should be methodical and prolonged."

Also this, from the *Gazeta de Camfimas*:

"We have been favored with the thesis which was presented and defended before the Faculty of Medicine of Rio de Janeiro by our fellow-provincial, William Ellis, a Doctor by the University of Pennsylvania in the United States.

"The subject of his essay is entitled 'Emphysema of the Liver,' into a discussion of which we shall not enter now, not only on account of our incompetency, but because this is a subject upon which men of science maintain silence, and about which there is much controversy. Dr. Guilherme Ellis was *approvado plenamente* by this Academy of the Empire, and proved his perfect preparation for the exercise of the noble profession of a physician in Brazil. We hope ardently for his prosperity."

It is worthy of notice that of three European graduates examined at the same time, one was rejected, and two *approvado simplesmente*, the inferior grade to that accorded to Ellis; which facts are rather rough for the theories of the editor of the *Times*.

Yours,

DR. W. H. WINSLOW.

It seems a matter of sheer impossibility to make one's self understood. We have no especial theories upon the subject of medical education, but we have asserted and reasserted the following facts emphatically: to these we suppose Dr. Winslow refers in his closing sentence:—that this city offers the greatest advantages to those desirous of studying medicine deeply, but that such study is not necessary to obtain a diploma; that the real student will find here almost everything he wants, excellent teachers, abundance of clinical material, large libraries, a union of facilities very probably greater than exists in any other city in the Union,—but that the diploma is no *proof* that the possessor has availed himself of these facilities; the graduate of one of our schools is often a brilliantly educated man—but perhaps as often he is a blockhead, or at least an ignoramus.

The case of Dr. Ellis is in close concord with all that has been editorially written in the *Times*. We had the pleasure of knowing Dr. Ellis as an earnest, intelligent student, taking advantage of every opportunity, and, after graduating, serving with distinction as interne in one of our hospitals. Of course he passed a brilliant examination when he returned home. Such Philadelphia graduates we would back against the world.

W.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A CONVERSATIONAL meeting of the Philadelphia County Medical Society will be held December 9.

Dr. H. C. Wood will lecture on the Use of Electricity in Paralysis.

All regular practitioners of medicine in the city are invited.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM NOVEMBER 24 TO NOVEMBER 30, 1874, INCLUSIVE.

MAUS, L. M., ASSISTANT-SURGEON.—Assigned to duty at McPherson Barracks, Atlanta, Ga. S. O. 191, Department of the South, Nov. 25, 1874.

SATURDAY, DECEMBER 12, 1874.

ORIGINAL COMMUNICATIONS.

THE AGE OF WOMEN WHEN THE CAPACITY FOR CHILD-BEARING CEASES.

BY FORDYCE BARKER, M.D.,

Professor of Clinical Midwifery and Diseases of Women in the Bellevue Hospital Medical College, etc.

Read before the New York Medical Library and Journal Association, November 20, 1874.

THE period when the capacity for child-bearing ceases in women is often a subject of medico-legal inquiry; yet, up to the present time, the question is left very loose and undetermined in the standard works on medical jurisprudence. I have several times been called upon to give an opinion on this point, and in this paper I shall give my reasons for expressing the belief that the limits of the capacity for conception and gestation in women can be defined with sufficient accuracy to warrant the medical expert in the expression of a positive declaration. Yet so many wonderful and apocryphal stories may be found in the medical literature of the past, which can be and often are quoted as disproving the accuracy of such a declaration, that it seems important to settle the question whether science can pronounce with authority that such pretended facts must be false. A zealous advocate, who feels that the interest of his client warrants him in bullying, by a rapid series of questions, in a loud tone of voice as if to intimidate from lying, may irritate and embarrass a medical witness to a degree that will destroy the force of a well-considered and sound opinion. For example, the medical expert is asked such questions as the following: "Do you set yourself up as an authority on this subject? Did you ever hear or read of Haller, one of the greatest lights in medicine that has lived in any age? Do you think that he made a false statement when he declared that he delivered one woman in her sixty-third and another in her seventieth year? Do you know anything of Tilt and Tanner as medical authors? What is your opinion of them? Now, will you say on your oath that they lie when they assert that Haller states that he did deliver two women at these ages? Did you ever hear of Dr. Benjamin Rush, one of the signers of the Declaration of Independence? Do you not think him rather a respectable man, who would be likely to speak the truth? Then are you ready to swear that he did not when he says that Ann Woods married after she was sixty years of age and gave birth to a child ten months afterwards? Did you ever hear of such a work as Beck's Medical Jurisprudence? Do you pretend that T. Romeyn Beck in this great work states an untruth when he declares that Ann Cook, of Whitehall, in this State, at the age of sixty-four had a child, born in February, 1836?"

A thorough knowledge of the literature of the subject and of the physiological laws which must govern it, an imperturbable temper, and great care in giving

direct and simple answers to direct questions, and in avoiding the appearance of being a partisan advocate, will best protect the medical witness from the confusion and embarrassment of a false position.

Casper states "that every year cases come before us in which it is judicially inquired whether an aged woman, in her present marriage, or in a second one about to be entered into by her, may yet probably have children. Usually these are women approaching their fiftieth year, if they are not already far beyond it, and who have for long ceased to menstruate."* I suppose this question is a subject of judicial inquiry much less frequently in this country; yet every physician is liable to be called upon to testify in regard to this point. In two instances I have reason to believe that an opinion which I prepared at the request of eminent members of the legal profession served to avert scandalous litigation. In a third case, a woman said to be of weak mind and a confirmed opium-eater, wealthy by the rise of real estate in this city which she inherited, married a second husband when she was forty-nine years of age. She had no children by her first husband. At the age of fifty-eight she asserted that she was pregnant, and persisted in this assertion for nearly a year. Subsequently her husband and herself declared that she gave birth to a child, while in the country, during the summer, and a nurse and two other women were ready to swear to it, no physician being present at the time of the birth. Three months after this alleged delivery she was one morning found comatose, and died a few hours after, the death being reported as due to apoplexy. The following summer the child died from cholera infantum. The husband claimed the property which she left, as heir to her child. This claim was contested by two nephews and the husband of a niece of the woman. The counsel for the contestants submitted to me a great array of medical opinion, which purported to show, from numerous examples found in medical literature, that women over fifty-eight years of age have given birth to children. Before the case came to trial, conclusive evidence was found to establish the fact that the nurse, and not the old woman, was the mother of the child in question.

Within the past year I have been called upon to give testimony in a case involving a very considerable amount of property, the case turning upon the point whether it be possible for a woman after her sixty-seventh year to conceive and give birth to a child. It was with regret that I felt it my duty to give an opinion, and my reasons therefor, adverse to that of several of my respected confrères.

My object in the present paper is to show that physiology and experience have determined the limits of the reproductive functions in women. It is generally assumed that the duration of the child-bearing capacity is coincident with the duration of menstruation. Most writers on forensic medicine, and most medical witnesses in the cases in which

* Forensic Medicine. The New Sydenham Society, London, vol. iii. p. 260.

I have been engaged, have referred to the numerous examples of menstruation prolonged beyond the usual periods of life as evidence that such women are capable of impregnation and gestation.

While it is generally true that when menstruation ceases the ovaries are no longer capable of furnishing mature ova for fecundation, and the uterus no longer has the power of retaining and developing an ovum, yet, on the one hand, thousands of sterile women menstruate regularly and normally, while, on the other hand, there are great numbers of women who have conceived before they have menstruated, and others who have given birth to a child some years after menstruation has ceased. Many cases, whose authenticity is beyond question, can be found in medical literature which demonstrate the truth of both assertions. I can furnish such which have come under my personal observation.

A lady in perfect health, except that she never had menstruated, was married at twenty. In the ten years following her marriage, I attended her in eight confinements. In 1870 I received a letter from her written in Switzerland, where the family have been living for some years for the purpose of educating their children, saying that she had not been exposed to the danger of having more children since the birth of her last child, then six years old; but that her husband was endeavoring to persuade her that she must be now safe, as she never had been unwell. I wrote in reply that, as she never had menstruated before the birth of her children, I regarded her as an unsafe subject for me to commit myself to an opinion on this point.

Another lady in this city, previous to her marriage, menstruated very scantily and irregularly. But in the twelve years since her marriage she has never menstruated, but she has given birth to ten children, and she is still keeping up her good work.

As an example that conception and gestation may occur some years after menstruation has ceased, I will mention the case of a lady in this city who had borne five children, the last at the age of thirty-eight. She ceased to menstruate at forty-two. Her health had previously been delicate, but she now became strong and well, and increased in weight over thirty pounds. When more than forty-six, I was asked to examine her, as she had felt many of the usual symptoms of pregnancy. I expressed the opinion that she was five and a half months pregnant; and my diagnosis proved correct, as in due time she gave birth to the finest and largest child that she had ever borne. In this case there was no motive for deception, and the result was a matter of family pride and rejoicing.

In November, 1851, I was invited by Professor Willard Parker to see a very curious and interesting case, which had been examined by several obstetricians. A woman, whose character was good so far as known, five years a widow, represented her age as forty-seven, and that she had not menstruated for three years. An abdominal tumor could be felt, reaching to the level of the umbilicus. An incessant convulsive movement of the abdominal integuments and muscles (phenomena sometimes, but rarely, associated with pregnancy, described by

Velpeau,* but hardly alluded to by any other obstetrical writer) rendered obstetric auscultation quite impossible and abdominal palpation wholly unsatisfactory. The mammary signs of pregnancy were negative. This woman gave birth to a child, supposed to be a little premature, the following March, and soon after died of puerperal fever.

Ovulation and menstruation, although often coincident, do not necessarily bear the relation of cause and effect, as has been supposed by many. Ritchie† and others have demonstrated by autopsies that ovulation does not always occur at the time of menstruation. Peaslee‡ remarks, "There is no proof and no probability that ovulation produces true menstruation. Certainly, ovulation, and even parturition, occurs in some women who have never menstruated. Menstruation is therefore an accidental and an incidental rather than an essential function, and it has no analogue in most of the lower animals. In itself considered, it is merely a flow of blood at stated periods from the interior of the uterus, irrespective of its connections and its causation."

Ovulation is absolutely an essential function for conception and gestation; but menstruation is not. Hence the numerous cases reported by medical writers, and quoted in works on medical jurisprudence, of a regular recurrent sanguineous flow from the genital organs in women over fifty-five years of age, no more demonstrate the possibility of conception in such women than does the same apparent menstrual discharge in women who have had both ovaries removed, of which there are several authentic cases.

When that physiological process takes place known as senile atrophy of the ovaries,—that is, when the ovaries diminish in volume, shrink up, and become wrinkled, the Graafian follicles disappear, the stroma becomes dense and non-vascular,—then ovulation ceases, and conception and gestation are no longer possible. All physiologists are in agreement in fixing the period of this change in woman as between forty and fifty. In a very exceptional number of women this change does not take place until one, two, three, or even four years later. This is proved not only by thousands of autopsical examinations, but also by the fact that not a single authentic case is known, of the slightest scientific value, where a woman over fifty-five years of age has given birth to a child, with the exception of Sarah, the wife of Abraham, in biblical history. Abraham was one hundred and Sarah was ninety years old when Isaac was born; and it is said "it ceased to be with Sarah after the manner of women." It is not surprising that Sarah, when she heard the announcement of her future pregnancy, "laughed within herself, saying, After I am waxed old shall I have pleasure, my lord being old also?" According to Scott's Commentary, "the name Isaac signifies laughter, and this child of promise was so named in remembrance of Abraham's believing and Sarah's unbelieving laughter."

From the time of Pliny down to the present day,

† Ovarian Physiology and Pathology, London, 1865.

‡ Ovarian Tumors, New York, 1872, p. 529.

there have been many cases reported in medical literature and quoted in works on forensic medicine, where women from fifty-eight up to eighty years of age are said to have given birth to a child.

But in a scientific inquiry I hold that we are bound to reject all statements which are opposed to the universal experience of mankind, when the probabilities against the truth of the assertion are at least as a million to one, unless it be supported by such evidence as would be regarded as conclusive in a court of law. Some of these reported cases have their only foundation in either tradition, travellers' tales, common rumor, or an anonymous paragraph in a newspaper or a magazine. Others again arise from a misquotation or a perversion of the original statement. The limits of this paper will not permit me to trace to the original source and analyze all of these cases, but I will briefly examine those which seem to have been accepted generally by writers on medical jurisprudence and by some recent obstetrical writers.

One of the earliest cases alluded to by many is given on the authority of "Pliny the Naturalist." Montgomery* says, "Pliny records the case of Cornelia, of the family of Scipio, who at the age of sixty bore a son, who was named Volusius Saturninus." Tilt† makes a somewhat different statement, as follows: "Cornelia was confined of Valerius Saturninus in her sixty-second year." It is sufficient to say, in regard to this, that the eldest child of Cornelia was born 163 B.C., and that Pliny was born 23 A.D. Consequently, one hundred and fifty years at least must have elapsed from the time of this extraordinary birth to the time when Pliny wrote; and, as he gives no documentary evidence in proof of his statement, it is safe to infer that it was derived solely from tradition.

Numerous writers assert that Massa, a physician of Venice (the name is variously spelled when quoted, as Marsa, Marra, Mansa), says "that he treated a woman for dropsy, who was really pregnant, he being deceived by her age, which was sixty." The writer referred to must be Nicholas Massa, of Venice, who died 1569. In his work,‡ in the "Epistola de aqua cutem seu hydrop," he speaks of a case in which a woman of sixty was treated for dropsy when she was pregnant, but he does not say that he was personally cognizant of the fact.

Many obstetrical and forensic authors refer to Valescus de Tarenta as "mentioning a woman who continued to menstruate beyond sixty, at which age she bore her last child." Valescus de Tarenta was a native of Portugal, born in 1382, and practised medicine in Montpellier, France. His work, "Practica quæ alias Philonium dicitur," can be found in that remarkable and valuable collection of medical books, the library of the New York Hospital, and perhaps some one who can read mediæval Latin with facility may take the trouble to ascertain exactly what he did say.

The weight of the great name of Haller has been

invoked in proof of the fact that women of advanced age have borne children. I find in many of the standard writers on this subject the assertion that "Haller delivered one woman in her sixty-third and one in her seventieth year." This curiously illustrates how books are filled with hasty, erroneous, and perverted quotations, for there is no evidence that Haller ever practised midwifery. He was born in Bern, 1708. In 1735 he was appointed physician to the hospital in his native town, but in 1736, when he was twenty-eight years of age, he was made a professor in the University of Göttingen, and from this time he gave up the practice of his profession. All that Haller ever said in his writings on this subject is as follows: "Women have been seen to bring forth in their fifty-fourth year, fifty-eighth, sixtieth, sixty-third, seventieth, and among my relatives was a child-bearing matron whose two sons born after their mother's fiftieth year, chosen into the senate, are living at the time of my writing this."§

Capenon is often quoted as an authority that women of an advanced age have borne children. But the only personal statement which he makes on this point is "that in Paris it passes for true that a woman in the street *La Harpe* gave birth to a daughter at the age of sixty-three."|| On which Casper makes the following comments: "Those acquainted with Paris well know the class of people living there: small shop-keepers, tradesmen, and the like. Are these observations possessed of the slightest scientific authenticity?"¶

The case of Ann Woods, who is said by Dr. Benjamin Rush "to have given birth to a child after she was sixty years old," is often referred to; but the evidence of the truth of the story rests entirely upon the assertion of the old woman herself, "who called at his house to beg for cold victuals," and at this time she claimed to be ninety-six.**

Another famous case, often quoted, is that of Ann Cook, of Whitehall, who is said to have had a child at the age of sixty-four.†† This story originated in an anonymous communication to the *Boston Medical and Surgical Journal*,‡‡ and is entirely unsupported by any evidence.

I think it wholly unnecessary for me to refer to various other reports of aged women who have given birth to children, which rest solely on paragraphs in newspapers and magazines, as these are of no scientific value.

After the most careful and laborious research, I can find but one authentic case, based on the evidence of a respectable medical man, who carefully investigated the documentary proof of the fact, where a woman who has reached the age of fifty-five has given birth to a child. This case is reported by Dr. Davies, of Hertford, England.§§

‡ *Elementa Physiologiæ*, Bernæ, 1765, tomus vii. pars ii. p. 141. I give the passage in the original, with the authorities which Haller cites: "Peperisse visæ sunt feminae anno 54(c), 58(d), 60(e), 63(f), 70(g), et inter consanguineas meas fuit patritia matrona, cujus duo filii post quinquagesimum matris annum nati in senatum adlecti supervivunt dum hæc scribo." ‡ *Epistolæ Medicinales*, Venet., 1549.

There are a considerable number of cases which must be accepted as authentic, as the evidence is conclusive, that women between the ages of fifty and fifty-four have borne children. I have personally known three women over fifty years of age who have become mothers. One case, which came under my observation, is so curious that I may be pardoned for relating it, as it is well known to many now living in this city.

May 6, 1852, I attended a case of labor in St. Mark's Place, in consultation with the late Dr. Robson of this city. The labor was normal but tedious, and our patient was delivered of a daughter by the aid of the forceps. This lady had been married twenty-seven years, and this was her first pregnancy. After the birth of the child, the husband showed to Dr. Robson and myself a family Bible, in which the birth of his wife was recorded as having been May 5, 1801.

July 3, 1853, Dr. Robson having died, I attended this lady in her second confinement. The mother and both daughters (now married) are still living.*

The question as to the age when the capacity for child-bearing ceases has been frequently brought before courts of law. In one instance only, so far as I can learn, it was decided that this is possible at the age of fifty-eight. François Fajat claimed an estate as heir to his mother. His claim was resisted on the ground that, according to the baptismal registry, his mother could not have been the legitimate heiress through whom the claim accrued, because her alleged mother would have been in her fifty-eighth year, and this, it was contended, was beyond the age of child-bearing. The court referred the case to the Academy, who, from the "Annals of Medicine," produced the apocryphal cases which I have before examined. The court admitted the legitimacy on the grounds that *menstruation* and conception had been known to occur at periods even later than this.† This was in Paris, in 1754.

The legitimacy of the claimant in the famous Douglas Peerage case, whose alleged mother at the time of his birth was in her fiftieth year, was decided in his favor. Until within a recent period, the English law has admitted "no presumption as to the time when a woman ceases to have children, though this enters into most other codes."‡ But at the present time the fact is otherwise. In the English Court of Chancery, the succession to a large property depended entirely on the question whether a woman at sixty years of age might have a child. The Attorney-General, Sir William Horne, stated that there was no such case satisfactorily recorded; and he offered to give up his client's title if any credible evidence could be produced in sup-

port of an instance. But, as none was brought forward, he was deemed to have succeeded in proving his claim.§

The English Court of Chancery seem now to have arrived at a definite conclusion as to the age at which a woman may be presumed to be past child-bearing. *In re Widows' Trusts*, Vice-Chancellor Malins made an order for payment to two ladies respectively. One of the ladies was a widow, past fifty-five, the other a spinster, aged fifty-three years and eight months. In both cases the parties were entitled absolutely, subject to the contingency of having children.||

In *Forty vs. Forty* (Feb. 1853), Vice-Chancellor Kindersley decided that an unmarried lady aged fifty-three might be presumed to be beyond the age of child-bearing. Taylor remarks, "The question may be considered definitively settled. A woman who has passed the age of fifty-three is presumed in law to be past the age of child-bearing."¶

I am not aware that this question has ever been judicially settled in our American courts. But, in conclusion, I feel warranted in stating the proposition that the laws of physiology, the experience of mankind, and the decisions of courts of law, justify a medical witness in declaring that a woman over fifty-five years of age is past the period of child-bearing.

TETANUS NASCENTIUM.

BY W. H. WINSLOW, M.D.

A WELL-DEVELOPED, rosy, hearty male infant, six days old, awoke at midnight, screaming, and the mother, in attempting to quiet him, found that he could neither hold on to, nor nurse from, the nipple; and, upon further examination, she discovered that the child had its lower jaw fixed, and its limbs rigid. The mother and several "old women" worked with him during the remainder of the night and the following day, trying to force down breast-milk, teas, and cure-alls, without success. Everything flowed from the mouth, and spasm after spasm finally awoke a spasm of sense, and started them after a doctor. I saw him at 6 P.M.

The women reported that the child had been delivered by a midwife, had had proper urinary and fecal evacuations every day, and had been perfectly well up to the time of the sudden nocturnal attack.

The parents occupied a very small room, with one window and door, in the second and upper story of a house upon the southwest side of which the heat on that July day was very oppressive, even after sunset. The perspiration ran from my face in streams while I made the examination. In this room had occurred her accouchement. Below was a low grog-shop; around the house the gutters were full of stinking slops and kitchen debris, and the Schuyl-

* The husband, whose age was fifty-four when his first child was born, was for many years captain of a New York and Liverpool packet-ship. I asked him how he explained the curious fact that his wife had now for the first time become a mother. His answer was that "he had followed the sea for many years, until he had got money enough to live as comfortably as he wished, when he concluded to stay at home and 'tend to his family duties.'"

kill, at no great distance, hinted of malarial influence. The dietetic supplies for the mother were coarse and inappropriate, and she, having passed her labor without mishap, had abandoned her bed on the fifth day. She was a blonde, with freckled, sallow, pock-marked face, and large blue eyes, of medium size, tolerably well developed, but one whose form, bride as she was of a year, spoke of tangents and secants,—*i.e.*, angular. Her age was twenty-two years.

The husband, one year her senior, was of medium size, brown hair and eyes, and most powerfully developed,—a condition which his labor as carter promoted and maintained. His health was perfect, but he had lost several fingers of his right hand by a circular saw in March, which accident had greatly shocked and distressed his wife,—then five months pregnant,—and had diminished their resources somewhat.

The first thing that attracted attention to the patient was the peculiar facial expression, and the intensely congested condition of the whole surface of the body. The skin was dry and hot. He lay upon his back, with head retracted, and eyelids so firmly closed as decidedly to resist attempts to separate them. The pupils were dilated, and did not respond to light; the lips were pressed firmly against the gums, making the mouth a slit about a quarter of an inch wide in the middle; the corners of the mouth were slightly drawn downwards, the tongue was pressed between the gums anteriorly, and foaming saliva filled the aperture, constantly flowing inwards and outwards during inspiration and expiration.

The lower jaw was so firmly fixed by its muscles that I could not move it by exerting all the force I dared to use. A space existed between the gums just sufficient to permit the introduction of the end of my index-finger. It seemed just wide enough to contain the teeth, had they been developed.

The patient's bowels had not been moved for eighteen hours, and he had not taken any nourishment since the beginning of the attack. The nostrils were dilated and immovable. The arms were drawn inwards, so that the elbows were within the marginal line of the body and could not be drawn outwards by the exercise of much force; the forearms were strongly pronated, flexed at an angle of 130° on the humeri; the hands were slightly extended, abducted, and brought nearly together at the middle line, with the fingers clenched and the thumbs *outside* of the fingers. This position of the thumbs is normal during the latter part of intra-uterine life, and is not departed from during the earlier weeks of external existence, because it requires time for the flexors to relax from their constrained ante-partum condition, and for the extensors to gain power to overcome them and produce equilibrium. The positions of the arms reminded me strongly of the pugilistic attitudes of children when they first mimic their elders.

The thorax was elevated and rounded, as at the end of inspiration, and remained so; while the abdomen was projected and tympanitic. The thighs were only slightly flexed on the pelvis, and

the legs on the thighs. The feet were extended extremely, and strongly abducted, and the inner malleoli were almost in contact. The great toes were abducted from the other toes, which were flexed, but their first phalanges were extended on their metatarsi.

Some one has said that the arm should be studied with the palm upon the ground, and pronated, in a position representing the fore-leg of a quadruped. If this patient's arms had been so placed, we would have found, upon comparison with the legs, that corresponding groups of muscles in the two members were affected in like manner and degree, and that in those groups which are most used and most powerful in life the tension seemed greater, while, all the muscles being contracted, the positions of the bones (other things not interfering) indicated the balance of power,—the resultant of all the forces.

The muscles were everywhere in tonic contraction, yet every moment there would occur a quick jerk, a letting-go-and-taking-hold-again movement, apparently from renewed nerve-irritation, which caused more rigid tension. If this movement were to be represented in diagram, it would not differ much from that of the healthy pulse as indicated by sphygmographic tracings. The infant's respiration was 50 per minute, very short and superficial; the expiration instantaneous, and he struggled for breath with his lungs full of air, like a patient with severe emphysema. The pulse was 140 per minute, thready, or, rather, corded, and distinct. He could not close his lips around the nipple, or swallow any liquid from a teaspoon, and every attempt with either only increased the violence of the spasms. He cried in an irregular whining manner, and remained in the spasms for ten minutes. Upon examining the umbilicus, the cause of the mischief was immediately apparent. There existed a hernia about the size of an English walnut, with thin walls, much congested, the redness forming an areola around the retracted and inflamed cicatrix of the funis. Pressure applied to the umbilicus only elicited most distressing cries and a more rigid contraction of the muscles. From careful examination I felt certain that the inflammation extended along the vessels of the cord inwards. Upon reducing the hernia, the spasms ceased immediately; and upon letting the projection occur again it immediately supervened. Here was an important fact in reference to the etiology of the disease, as well as a hint to the doctor. I kept the hernia reduced, and put him to the breast. The moment his lips were pressed against the moist nipple, the spasm returned again. A salt-and-water injection brought away a yellow stool of moderate quantity; a warm bath was given; the umbilicus was dressed with cerat. plumbi and carbolic acid upon a pad, kept in place by a bandage, to keep the hernia reduced. After this the spasm yielded, and a little milk was swallowed from a teaspoon several times, when suddenly a puff of wind from a rising storm came in at the window upon the little patient, and he went off into another spasm. Three powders, each containing res. scammonii gr. $\frac{3}{8}$, and hydrarg. chl. mit. gr. $\frac{1}{4}$, with sugar, were ordered,

one to be given every two hours, and potass. brom. gr. ii, in solution, were directed to be given every alternate two hours.

The next morning, at nine o'clock, I found the patient had been convulsed part of the night, had not slept, but had taken medicines, and some milk from the spoon. He could not close his mouth upon the nipple, and the attempt intensified the trismus. Bowels had moved freely. The facial expression and spasmodic condition were the same. Cheeks were cool and cyanosed, the cerulean hue somewhat mixed with erythema of the skin extended over the trunk. Sudaminae over the neck and breast. Umbilicus felt and looked cooler and better. Respiration was 90 and the pulse 150 per minute. Ordered ext. physostigmæ, gr. $\frac{1}{4}$, sod. sulphit. and quin. sulph. ãã gr. i, in solution, to be given every two hours; ungt. belladonnæ to be applied to the spine, and the nourishment with brandy to be pressed. The third day friends reported that the patient had been very bad all the day before, but had passed a quieter night, and taken medicine and food as directed. General appearance was much the same. The intervals between the spasms were more frequent and more prolonged. The cyanosis was more marked over the extremities, and the cries were more feeble. Respiration was 106 and pulse 180 per minute. Hernia was still reduced, and doing well. When the child was put to the breast, spasm came on, but milk given in the spoon was sometimes swallowed, sometimes rejected. The tetanic symptoms were better, but patient was becoming weaker. During the spasms a white fluid (milk) was regurgitated from the stomach freely, so that what was gained between spasms was lost during their continuance. Treatment was continued, but the physostigma was increased to gr. $\frac{1}{2}$ every two hours.

The fourth day I found the child in convulsions, which had been very bad since the previous evening, so that no nourishment or medicine could be taken. Fæces and urine had been voided during the night. Face looked old, wrinkled, and blue. The surface of the body everywhere was sodden and dark from venous congestion. The jactitations of the muscles kept fists moving comically. Limbs resisted forcible attempts to change their positions. Arms drawn outwards a little, sprang together again when released. Umbilicus looked almost well, but I squeezed out a drop of pus from below the cicatrix. Oral aperture was filled by saliva and the point of the tongue. Eyelids were closed, but pupils dilated. Respiration was 130 and pulse 200 per minute; the latter determined imperfectly by ear over the heart. Continuous convulsions existed till 5 P.M., when the child died. Parents would not permit a post-mortem. These cases being so rare, I took my notes by the bedside, that the data might be reliable. I desire attention to the following summary. The bad hygienic conditions surrounding the case, the fright of the mother at the fifth month, and the pathological condition of the cord, may all be regarded as causes: the first two predisposing, the last one exciting. The attack came on between the third and tenth days, which is the rule.

The convulsions affected the whole of the muscles at once. There was little opisthotonos, because the ante-partum flexion had not yet been counter-balanced. There was eagerness but inability to take the breast, except during the relaxations or intervals; and even then the act seemed to excite spasm quicker than any other. Food and medicine were given and retained during the earlier intervals, but regurgitated during spasms later. Pulse was accelerated when first seen, and increased much as the disease progressed; contrary to the statements of authorities, "that it is diminished." The bones of the head were not displaced, and no diarrhœa occurred. The whole duration of the disease was eighty-nine hours. When the hernia protruded, convulsions came on immediately; when the tumor was reduced, they temporarily ceased: this, in connection with the inflammation of umbilical vessels and the drop of pus, excludes pyæmic and centric causes, and brings out clearly peripheral irritation as the principal factor. It will be noticed that my therapeutics were directed to all three. My next case I shall treat in the main locally.

3729 LOCUST STREET, WEST PHILADA.

REPORT OF AN OPERATION FOR LACERATED PERINEUM—UNION FOLLOWING FAILURE OF THE ANAL SUTURE.

BY J. J. MAGUIGAN, M.D.

MRS. McF., a healthy young woman, 23 years of age, was confined in a small village in the State of Michigan, at full term. The presentation was cephalic, occiput front. During the long, difficult parturition the perineum gave way with a violent pain which expelled the head, the rent extending through the sphincters into the rectum. The child was dead.

The accident entailed incontinence of flatus and fæces. With this disgusting infirmity upon her she again became pregnant. In due time I delivered her in this city, without accident, of a healthy male child.

Six weeks after the parturition, I undertook the operation, in which I was kindly assisted by Drs. Wilson, Buckley, and James A. Maguigan. Her bowels were unloaded the preceding day with a dose of castor-oil, after which a two-grain pill of opium was given. Being thoroughly etherized, she was placed in the usual lithotomy position. The operation was rendered extremely difficult by the absence of one of the attendants expected, and was fitfully and hurriedly performed. The vaginal surface of the septum was freely denuded of its mucous covering for an inch of its extent. The lacerated surfaces were next pared off, the incision commencing below and taking off a thin border from the labium. In breadth it extended to the vaginal mucous membrane. Three sutures of silver wire were employed. The needle, armed with the first suture, was made to enter three-fourths of an inch from the margin of the wound just below its lowest point, and, traversing its entire depth, was brought out on the middle of the septum, just above the line of denudation. The needle, being now disarmed, was withdrawn and made to enter on the opposite side at a corresponding point and to emerge on the septum close to the first. Now, the evident design of this thread is to draw tightly together the vaginal septum and the oval extremity of the wound and hold them in this close contact until the resulting

inflammation unites the parts in one and restores the integrity of the sphincter ani. This is its grand aim and function. Great importance is consequently attached to the proper disposition of this suture. But the authority which teaches that the fate of the operation hangs on this stitch, that if union be primarily defeated here, though the rest of the wound have united throughout, the operation cannot be viewed in any light other than that of an absolute failure, is an error. The truth of this proposition, which is not unfairly stated, will be exemplified in the sequel. The two other sutures were placed equidistant, the last near the top of the wound. The parts were closely approximated, and the opposite ends of the wire were brought together and secured by compressed shot. Interrupted sutures were superficially deposited between them. The operation was now finished. The external aspect was handsome. I explored the interior, and, to my chagrin, found a communication between the anus and the vagina. Across the chasm, stretched hard like the string of a bow, the wire could be distinctly felt. I saw that in my haste I had on one side (the left half) passed the wire directly across the vaginal face of the septum, instead of behind it as I was pleased to declare in a foregoing sentence. I feared for the success of the operation, but was not inclined to open up the wound again. I satisfied myself with the hope that the opening would close up by granulation during the progress of the inflammation.

I attended to the after-treatment myself, with the most scrupulous exactness in its many details. I drew off her urine with a catheter twice daily for the first few days; after this she relieved herself by turning forward on her side. I syringed the parts daily with a detergent composed of carbolic acid and water. Her bowels were kept quiet with opium. Nutritious food—beef-tea, eggs, and milk, articles which leave little residuary matter to fill up the bowels—was freely administered. Her knees were confined with a bandage. I had the good will and co-operation of the patient, and the support and encouragement of her sensible mother. Everything indeed seemed to work in the most harmonious accord, with a hopeful promise.

On the sixth day, finding that the sutures had outlived their usefulness, I removed the two anterior ones and found that the union was here complete. I let the posterior stitch remain until the following day, but as it was then clearly of no further service I removed it. The wound gaped at the anal aperture, and revealed a channel of communication between the anus and the vagina large enough to admit the point of the finger. Here there was certainly a failure of the first stitch, and consequently of the operation. I hesitated to communicate the mortifying intelligence to my patient. I stated my case to Philadelphia's great perineal surgeon. He gave me little hope. I requested him to examine the case before passing judgment. This he kindly consented to do. After exploring the parts, he declared in the most positive manner that the result was destitute of any value, and that the whole perineum would have to be opened up again, and advised a new operation. With this crust of comfort he left me. Now, to my mind (as well as to my eye) it seemed clear that the operation which I had done had resolved a bad case of perineal laceration into one of simple anal fistula with division of the sphincter ani. I recognized the case only in its new relations, and treated it as the primary and essential lesion. I touched the fistulous track with a crayon of nitrate of silver. I returned in a week, and found, to my delight, that the track was nearly closed. One more touch with the *lapis mirabilis*, and the parts came nicely together and cicatrized. The patient's recovery was simultaneously proclaimed.

1241 NORTH SEVENTEENTH STREET.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

SERVICE OF R. J. LEVIS, M.D.

Reported by Dr. JOHN B. ROBERTS.

TETANUS RESULTING FROM GUNSHOT WOUND OF THE ARM TREATED BY HYDRATE OF CHLORAL.—CONVALESCENCE OF THE PATIENT.

WILLIAM T., aged 19, while gunning, was shot in the left arm by his own fowling-piece, the contents of the barrel tearing away the inner side of the arm and fore-arm for about six inches, and burying themselves in the tissues of the arm.

Upon admission, there was a good deal of hemorrhage from the wound, but the ulnar and radial arteries beating naturally at the wrist showed that the shot had not cut into the brachial artery. The wound was dressed with solution of carbolic acid and oil; but in a few days it assumed an erysipelatous condition, and the arm became much swollen and gave the boy severe pain. The treatment was continued, with the addition, however, of lead-water and laudanum locally, and iron and quinine internally.

Under this treatment the wound gradually assumed a more healthy appearance, large quantities of shot and wadding were discharged from its upper angle, the patient felt comfortable, and all things progressed favorably. On the fourteenth day, however, there came a change, and at the morning visit there was noticed a slight stiffness of the jaws, and some rigidity of the recti abdominis muscles, showing conclusively the advent of tetanus. The patient had great difficulty in eating, and, when asked to open his mouth, could scarcely separate his jaws, so that he could only receive liquid nourishment.

In a day or two these symptoms increased, so that the boy complained of pain in the posterior cervical region and along the spine, and of having bitten his tongue several times by the spasmodic snapping together of his teeth.

At the first intimation of tetanus the treatment adopted was ten grains of hydrate of chloral every two hours, with occasional doses of morphia when the pain was very severe. The object was to get the patient thoroughly under the influence of the chloral, and to keep him sleeping the greater part of the time. Accordingly, the frequency of administration of the drug was varied as circumstances indicated; sometimes the dose raised, at others the ten grains given every hour or hour and a half, while occasionally the interval was increased to three hours; the boy receiving, on an average, about one hundred grains during the twenty-four hours.

Under this treatment the patient was quite comfortable, and slept much, but there was no relaxation of the tonic spasm, and the muscular rigidity gradually increased.

Four days after tetanic symptoms first presented themselves, Dr. Levis, although the great gaping wound looked healthy, opened up the parts, in order to ascertain whether any wadding or shot yet remained imbedded in the tissues, and tore open the inter-muscular spaces with the finger, lest there should be irritating pressure exerted upon some of the nervous trunks of the arm. No foreign material was found, and, after the tension had been thus relieved, the limb was enveloped in a large poultice.

The symptoms continuing, it was thought that amputation might possibly afford a chance of relief, but, after consultation, it was decided that the removal of the limb at this period, after the nervous centres had been so certainly involved, was a step of too doubtful pro-

priety. Accordingly, the chloral-treatment was steadily persisted in, notwithstanding that diarrhoea occurred on the sixth day, whether or not produced by the drug it is difficult to determine. This looseness of the bowels was controlled by camphorated tincture of opium.

The trismus continued about the same, the dorsal muscles became more and more contracted until opisthotonos was very marked, and the patient became unable to empty his bladder. During this time, however, there were no spasms and no difficulty in deglutition, for the food readily passed into the stomach after it was placed in the mouth.

Traumatic tetanus seems to occur more frequently in young than in elderly subjects, and may follow the receipt of various injuries, often occurring after the most trivial. Dr. Levis has had the disease supervene after frost-bite, and even in a case where issues were made by Vienna paste for the cure of varicose veins.

In this case the tetanic symptoms first noticed in the masseter and temporal muscles did not present themselves until the fourteenth day after the receipt of the injury, though the affection often shows itself much earlier.

The face of the patient has an anxious expression, is moistened with perspiration, and the skin of the forehead is traversed by wrinkles; these signs constituting the characteristic physiognomy of tetanus. The muscles of the jaw are generally involved first,—whence the name of locked-jaw,—and then the posterior cervical muscles; afterwards the abdominal and dorsal, and finally those of the extremities, show rigidity; whereas the hands, and particularly the feet, seem to escape the tonic spasm.

In this case, owing to the chloral administered, the pain and stiffness increased gradually, without any positive tetanic spasms; although occasionally there were slight paroxysms in which he bit his tongue. For this reason he held between his teeth a piece of leather, to prevent injury to his tongue during the spasmodic snapping of his jaws. It is worthy of remembrance that it may be a dangerous experiment to ask a man with tetanus to protrude his tongue for inspection. A case recently occurred in the hospital in which the jaws shut down upon the tongue as it was thrust forward, and were separated only with great difficulty and after severe laceration of the member.

The prognosis of this, as of every case, was, of course, unfavorable, but when the patient had survived for two weeks since the advent of tetanus, it was thought that he might perhaps recover; for it has been frequently observed that the mortality is much less in those who have been kept alive until after the tenth day.

The treatment of this nervous affection is exceedingly unsatisfactory, and almost every remedy of the materia medica has been employed. Opium has long been considered the most efficacious; but so long as nearly every case of traumatic tetanus proves fatal, the search for some more potent remedy must be continued. Dr. Levis has seen three cases recover under the use of large doses of chloral, one under physostigma, and one under bromide of potassium in combination with chloral.

The chloral-treatment has been lauded so highly of late that it was thought well to test it in this case. Death occurs usually from asphyxia caused by laryngeal spasm, and it is probable that the chloral does nothing more than prevent the occurrence of spasms, and thus lessen the chances of suffocation.

* * * * *

At this time—five weeks since the trismus was first observed—the patient is convalescing, and, unless something unforeseen occurs, will steadily improve. There is little or no pain in the dorsal muscles, the opisthotonos is lessened, and he is able to separate his jaws wide enough to allow a thumb to be passed be-

tween the teeth; while the wound in the arm has filled up with granulations, is without pain, and rapidly cicatrizing.

Dec. 10.—The patient is now well.

ALLGEMEINES KRANKENHAUS, VIENNA.

CLINIC OF PROF. CARL BRAUN, OCTOBER 28, 1874.

GENTLEMEN,—We bring before you to-day a woman 35 years of age, who since yesterday has been in labor. Physical examination shows a pulse of 60, regular and strong; skin moist and cool, and the temperature of the body normal. On inspection, we find an abdomen much more than usually large; while a large tumor is found in the left inguinal region. The fundus uteri is strongly inclined to the right, and palpation reveals the uterus in a state of tonic contraction. What is here the cause of difficulty? Why does not the head pass into the pelvis and labor come to a natural and easy termination? A vaginal examination shows the pelvis rather more than usually small; but in every portion it is perfectly regular, and can by no means be termed a *contracted* or *narrow* pelvis. The cervix is very much elongated, and with two fingers introduced I am unable to reach the internal os. Meconium is present, a sign which we are often led to associate with difficulty or danger; and it is evident that the child is making fruitless attempts at respiration. On measuring the length of the child, which we can readily do by placing one hand over the fundus and the other over the head, upon the surface of the abdomen, or by its introduction into the vagina, making in all cases allowance for the intervening tissues, we find it to be about eighteen inches. Having ascertained its length, we can then estimate its weight; for the length of the child in utero and its weight, *as a rule*, bear to each other a definite relative proportion. The length of the child may be ascertained in the manner already mentioned as early as the fifth month. From this until the tenth month the child attains an increase in length of two inches for every month, and, if we reckon according to Austrian pounds, an increase of one pound for each month, so that we have such a table:

5th lunar month	=	10''	=	1 pound.
6th " "	=	12''	=	2 pounds.
7th " "	=	14''	=	3 " "
8th " "	=	16''	=	4 " "
9th " "	=	18''	=	5 " "
10th " "	=	20''	=	6 " "

An examination of the head, which we find to be the cause of the large prominent tumor in the left inguinal region, shows it to be very large, measuring certainly four or five inches in diameter. A vaginal examination also reveals the presence of very wide sutures, the sagittal suture measuring fully an inch in width. Here, then, we find the cause of this delayed labor, viz., hydrocephalus.

What, then, shall be our treatment, and what is our prognosis? Of one thing we are certain: this child cannot be born without the assistance of art, and hence we must make an attempt to help. Delay can bring no release to the mother, whose forces are gradually diminished as the period of delay is lengthened. If left alone, the case will terminate in one of two ways: either in metritis with fatal termination, or in rupture of the uterus; and the latter is most frequent when nature is unassisted. Shall we wait for the expansion of the os? No. As already said, the cervix is several inches in length; the internal os being situated opposite a point four inches above the mons; while the head stands on the brim of the pelvis, unable to enter. Turning is not practicable. The application of the forceps can

avail nothing; such an attempt would result in complete failure, and you would withdraw your instrument empty.

The treatment applicable in such cases, and which we will here make use of, is as follows: Introduce the left hand, grasp the head so as to hold it firmly in position, and then, passing a trocar along the palmar surface of the hand and fingers, so as to avoid injuring the tissues of the mother, introduce it into the cranial membranes, and withdraw the fluid. I prefer here a long and curved instrument, which will adapt itself to the curve of the pelvis. I would not, in such cases, perform craniotomy; not, however, because I think, as some assert, that any other course of procedure might lead to the birth of a child having the capability of living any considerable time. When not certain of the existence of hydrocephalus, you can apply the forceps, and make an attempt at extraction. It has also sometimes a good moral effect, while in the eyes of parents and friends it seems less barbarous than opening the cranium; and when you fail, as you must in hydrocephalus, you can proceed to puncture and deliver. The size of the head may be measured by the forceps. Introduce the blades, placing them in position, and measure the distance of the handles apart; then, removing, place them again in the same relative position to each other, and measure the distance between the blades. Applying that instrument, we find a diameter of four and one-half inches for the head. Introducing a trocar, we withdraw the fluid characteristic of hydrocephalus, a thin, transparent, watery liquid, measuring in this instance one and a half pints.

In these cases the great size of the head, still remaining after the withdrawal of the fluid, may offer a serious obstacle to delivery, and resort to the forceps or cranioclast is frequently called for. A resort to the cranioclast is always attended by a very unpleasant sensation to the operator. The movements of the child, indicative of the pain it suffers, can be distinctly felt, and it is no pleasure to know that you are thus destroying the life of a human being.

Since the withdrawal of the fluid, we find the relation of the uterus to the pelvis and the abdomen entirely altered. The head, which before presented such a large tumor in the left inguinal region, has receded; and the fundus, instead of lying so far to the right, has returned to the median line.

We here leave the case for the present to the efforts of nature, which it is hoped will prove all-sufficient for delivery during the lapse of a few hours.

G. WILDS LINN.

TRANSLATIONS.

ON THE SO-CALLED SPONTANEOUS REGENERATION OF NERVES.—Under this title Prof. Vulpian contributes to Brown-Séquard's *Archives*, Nos. 4 and 5, 1874, a communication, in which he modifies certain statements made by himself some years ago, relative to the regeneration of nerves.

Experiments were made in 1859 by Vulpian and Phillipeaux, who removed entirely the central part of certain nerves, so that it seemed impossible that any communication whatever could be established between this portion of the nerve and the peripheral segment.

It was found, however, that after becoming atrophied to a certain degree the peripheral portions of the nerves operated upon became the seat of an active process of regeneration. A large number of nervous fibres reappeared little by little, with all their normal characteristics. In certain nerves, as the hypoglossal, the regeneration at times seemed almost complete.

This took place although the hiatus established by excision between the central and peripheral portion continued complete. The researches of Waller had proved conclusively that every nervous fibre separated from its trophic centre would not only atrophy, but would never become regenerated unless put in connection with such trophic centre by reunion or reproduction.

"Our researches," remarks M. Vulpian, "seemed to prove that the propositions formulated by Waller had been too sweeping, and we concluded that the maintenance of the structure of nerves only depends in part upon the influence of the central nervous system;" "that altered nerves may become regenerated or restored without the intervention of an influence emanating from the nervous centres;" and, finally, "that nerves separated from the nervous centres may, even while they remain isolated from these centres, recover their normal structure and properties." "Although I believe that we took every precaution against error, I cannot go over the various details, but will confine myself to a few words relative to the experimental results which have led me to retract, on my part, today, the assertions formerly made by us relative to the autogenetic regeneration of nerves."

M. Vulpian then goes on to speak of certain confirmatory experiments. Having cut out a portion of the hypoglossal nerve of a dog, he found that after some months the motor power was still retained. He then made a deep incision at the initial end of the peripheral portion, sweeping the knife around so as to cut off any accessory filaments. On microscopic examination of this portion a week or so later, he found that, with the exception of a very few fibres, the nerve remained unchanged.

This seemed to prove almost conclusively the fact of autogenetic regeneration, since this regeneration could not be explained as apparent and depending upon anastomotic filaments, for these had been cut.

Further experiments, however, were made, which caused him to arrive at a different conclusion. When the peripheral portion was not only separated, but this process of isolation was carried some distance along its course, it was found that the motor power was almost entirely destroyed, and that under the microscope the nervous filaments were visibly altered. It seemed to result from these experiments that the peripheral portions of the hypoglossal or lingual nerves, after the excision of a part of their length, only became regenerated because certain of the filaments and nervous tubes connected with these peripheral portions, and which had been cut during the operation, became united and reassumed their continuity. Anatomico-physiological relations were thus established between these nerves and the nervous centres by the intermediation of other nerves in the neighborhood.

The number of tubules in the anastomotic branches is always less than the number of tubules in the peripheral portions of the nerve which become regenerated. It is probable that each of the fibres which restore to the peripheral portion of the nerve the trophic influence of the nervous centres may give rise to several new fibres, or transmit this influence to a certain number of old fibres with the result of arousing in them the regenerative evolution.

If the new interpretation which is now proposed for these facts observed in 1859 is correct, it will be seen that the trophic influence of a nervous centre may be furnished to a nerve by another region of the gray substance than that from which that nerve takes its origin.

This proposition has already been proved by experiments made by MM. Vulpian and Phillipeaux on the end-to-end reunion of nerves of different origin.* It

* See Med. Times, April 25, 1874, p. 472.

seemed permissible to conclude from these experiments that the trophic influence of the nervous centres had been transmitted to the peripheric portion of the hypoglossal by the essentially sensitive fibres of the lingual nerve; and, as a consequence, that the region of gray substance where the sensitive fibres, those of the linguals, originate, may serve to maintain its integrity of structure of the fibres of the hypoglossal,—that is to say, of motor fibres.

Certain reservations, however, must be made in drawing conclusions from these facts, since the hypoglossal is far from being a simple nerve, and also because it anastomoses to a certain degree with adjoining nerves. The interpretation of these facts is beyond doubt very difficult.

M. Vulpian concludes: "Recent experiments which I have made in the regeneration of the peripheral portion of the hypoglossal after exsection of the central part of this nerve enable me to assert that this regeneration does not take place in an independent manner and without any influence on the part of the nervous centres. It appears to come about by the mediation of fibres, anastomotic or other, which, in regaining their continuity, place the peripheral portion of the hypoglossal nerve in anatomico-physiological relation with these centres."

The same explanation would answer quite well for all the other facts of so-called autogenetic regeneration observed after removal of the central portions of the facial or spinal nerves, etc.

Certain nerves, as the sciatic, having few anastomoses, become regenerated but slowly, and at best but to a slight degree; even some months after exsection of a portion of the sciatic in a rabbit, only a small number of regenerated nerve-tubules were found in the peripheral portion of this nerve.

The laws of Waller, therefore, reassume their entire and absolute value; and in nerves, the nervous fibres provided with myelin do not preserve or recuperate the integrity of their structure during extra-uterine life, and above all in adult animals, but on the condition of being in relation, the one (sensitive fibres) with the ganglions of the posterior root, the other (motor fibres) with the gray substance of the cerebro-spinal axis.

A. V. H.

PREVENTIVE AND EXPLORATORY TREPPANNING IN FRACTURES OF THE INTERNAL OR VITREOUS TABLE OF THE CRANIUM.—M. Sédillot read a note on this subject before the Académie des Sciences at a recent meeting. His conclusions were as follows:

1. Preventive trepanning is the surest method of treating all fractures of the internal table of the cranium complicated by splinters.

2. The operation is demanded in cases of external stellate or linear fracture with depression of the cranium.

3. Hesitation is permissible in simple linear solutions of continuity without displacement of the bones.

4. The means of diagnosis comprise the causes of the traumatism, symptoms, auscultation, percussion, thermometry, and of explorative trepanning.

5. The absence of any exterior fracture does not contra-indicate the possibility of an internal one, following direct traumatisms of a circumscribed or violent nature; and if auscultation and percussion, the force of the blow, the nature of the wounding body (gunshot wounds) do not indicate the necessity of exploratory trepanning to the surgeon, it is his duty to watch the patient carefully, and to have recourse to this operation without delay, where new symptoms indicate the opportunity. This is understood to be in localities exempt from infectious influences which experience shows to be constantly fatal in similar cases.

6. Precautions and dressings founded upon the theory of ferments will modify, perhaps, this inability to operate, and seem already to promise most favorable results in wounds of the cranium.—*Gaz. Méd. de Paris*, Oct. 24, 1874.

CHLORAL AS AN APPLICATION IN GANGRENE.—M. Dujardin-Beaumetz communicated to the Société des Hôpitaux, at a recent sitting, an account of the case of a young man 18 years of age, who applied for relief for spontaneous gangrene affecting the hand and fore-arm. In order to dissipate the odor and to avoid the danger of septicæmia as far as possible, M. Beaumetz had the affected limb kept constantly in a bath containing one part chloral to five hundred parts water. At the end of eight days the arm was amputated, with a favorable result.

A. V. H.

CONGENITAL ABSENCE OF THE BLADDER—INCONTINENCE OF URINE—CATHETERIZATION—DEATH FROM PERITONITIS.—At a recent meeting of the Société de Chirurgie, M. Gyon read for M. Fleury the following observation:

A young girl who had menstruated since about a year previously, entered the hospital at Clermont for incontinence of urine of some months' duration. The vulva and the upper portion of the thighs were the seat of a painful erythema. A sound introduced into the canal of the urethra did not penetrate more than about an inch and a quarter. The vaginal touch showed relaxation of the vulvar ring, but furnished no further information.

Her general condition was good. Examination with the speculum was postponed until the following day. At that time the patient complained of pain in the belly; the skin was hot, the pulse frequent. The catheterization had been carefully made, and these symptoms could not be accounted for. They increased in severity, and the patient succumbed a few days later.

The autopsy revealed an effusion of pus into the abdominal cavity, covering the folds of the intestines. The bladder was entirely absent, the ureters terminating on the sides of the urethral cul-de-sac. The left kidney contained creamy matter of a whitish-yellow color; the right kidney was healthy. It was difficult to explain how, with such a vice of constitution, the incontinence dated back only one year; later, however, M. Fleury learned from the patient's mother that this infirmity was congenital, but that it had become insupportable only within the last year. It is possible that within this time the urine had acquired an acidity which brought on the erythema.—*Bull. Gén. de Thérap.*, Nov. 15, 1874.

HYDATID CYST OF THE LIVER RELIEVED BY ASPIRATORY PUNCTURE.—At a recent meeting of the Société des Hôpitaux, M. Dumontpallier communicated the following case:

A patient, after having presented for some time the various symptoms of dyspepsia, showed signs of a chronic pleuritic effusion on the right side. A series of blisters were applied, and aspiratory puncture was proposed,—the diagnosis of hydatid cyst of the liver having been arrived at. The proposal of this treatment was negatived at the time by the patient and the consulting physicians. Some time afterwards the dyspnoea became very distressing; puncture was again proposed, and was practised with a No. 2 Potain's trocar, about half an inch below the nipple. The exit of a transparent, non-albuminous liquid, containing the débris of hydatid sacs, was the result. The operation was followed by immediate relief, and resulted in complete cure.—*Bull. Gén. de Thérap.*, Nov. 15, 1874.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, DECEMBER 12, 1874.

EDITORIAL.

THE RIGHT MAN IN THE RIGHT PLACE.

THE pressure of original matter upon the columns of the *Times* is at present so great that we must defer considering the causes of the slow growth of specialism in this city; but we desire briefly to call attention to the recent appointment of coroner's physician, as an instance of a tendency to the belief that the less education upon a special subject a physician has, the more fit is he for a position involving special knowledge of that subject; or else of an almost equally indefensible tendency to select men not because they have special fitness, but because they are friends of the appointing power, or have some coveted influence.

Dr. Goddard, our new coroner, was elected largely through the efforts of the profession, because a medical coroner was wanted, and because it was believed that he would appoint such physician or physicians as, having a knowledge of medical jurisprudence, would gather important gleanings from their experience to add lustre to the medical fame of our city. We have a few men of ability who have devoted a great deal of attention to the subject of medical jurisprudence; but, instead of selecting them, Dr. Goddard has appointed two of our busiest and most popular surgeons,—men of the highest eminence in surgery, but destitute of any special training in, or knowledge of, medical jurisprudence,—men, too, so absolutely engrossed in public and private practice that it is absurd to sup-

pose they can study up the subject, or even attend to the mere routine duties of the position; of course the work will be done by deputies.

Dr. Goddard, knowing that his appointees are deservedly esteemed as surgeons, may have chosen them because he thought that they could influence the profession in his favor; but we think the Philadelphia profession will never stultify itself by endorsing such an appointment. If Dr. Goddard had selected Prof. Reese, or some other equally well-known special student of medical jurisprudence, he would have greatly strengthened himself; as it is, when, in the future, he wants most the sympathy and aid of his brethren, he will perhaps discover his mistake.

LEADING ARTICLES.

THE TRANSMISSIBILITY OF TUBERCULOSIS.

II.

IN our last article it was shown that tuberculosis may be communicated by inoculation. A still stronger corroborative proof that it is a virulent infectious malady is furnished by those investigations which have been made to demonstrate its wellnigh infallible communicability through the digestive canal.

It has now been settled beyond all controversy that the contagia of certain virulent diseases, when administered, can infect as readily through the digestive organs as through any other channel. This is especially true of variola crusts and pustules, and of the discharges from glanders and anthrax.

Chauveau, of the Lyons Veterinary School, with a view to ascertain whether phthisis was also transmissible in this manner, instituted a series of experiments by administering large quantities of tuberculous material. Deeming it essential that a species of animals should be procured in which tuberculosis was a spontaneous disease, endowed with the characters it presents in man, he therefore selected the bovine species, and, as a precaution to avoid experimenting upon animals already infected, he resorted to calves born and bred beyond all those influences or conditions which favor the natural development of phthisis.

Four calves were selected. One, which was kept for comparison, remained unaffected; the three others, fed upon tubercular matter, were in such a miserable state fifty-two days from the commencement of the experiment that it was considered time to kill them. The autopsies revealed the most perfect lesion of generalized tuberculosis, the mesentery and intestines being extremely involved. Peyer's glands were nearly all in a state of ulceration; besides, there was an eruption of tubercles throughout from the duodenum to near the termination of the colon. The lesions in the thorax were less marked than those of the abdomen; all the

bronchial and mediastinal glands were enlarged and diseased. Throughout, there was a marked predominance of the glandular over other forms of tuberculosis. To show that there was no analogy between this induced disease and purulent infection, Chauveau states that he has introduced with impunity large quantities of pus into the digestive canal. He concludes his important communication with this résumé of his experiments: 1. They prove that bovine animals contract tuberculosis by digestive ingestion, as they may take anthrax and vaccinia. 2. They place beyond doubt the fact as to the virulence and contagious property of tuberculosis, and show that the labors of Villemin have not been recognized as they deserve. 3. They show that the digestive canal constitutes in the bovine species, as in man, a channel of contagion readily disposed for the propagation of tuberculosis, and which may be more frequently the mode of access than through the pulmonary organs.

Gerlach, Böllinger, Zürn, Leisering, Harms and Gunther, Klebs, Bagge, Saint-Cyr, Pétróff, Vergad, besides other experimenters, have all succeeded in producing artificial tuberculosis by feeding tuberculous flesh and lungs, caseous lymphatic glands, etc., taken not only from phthisical men, but also from cattle and pigs spontaneously or artificially affected with the malady. The different varieties of animals chosen for these experiments were nearly as numerous as the varied investigators, so that now, besides rabbits and guinea-pigs, sheep, pigs, dogs, cats, and cattle may safely be said to be susceptible of acquiring tuberculosis by ingestion in the digestive canal. This long list of carefully-conducted experiments certainly justifies the conclusions as to the virulency of this affection, and must appear convincing to any but the most skeptical.

Of these investigations, those which were made with the cooked and uncooked flesh and milk of phthisical cattle are by far the most interesting and important in their practical bearings.

Böllinger, Gerlach, and Klebs, especially, have been successful in producing tuberculosis by giving animals milk from phthisical cows. In addition to rabbits and guinea-pigs,—creatures apparently very susceptible to the artificial production of the disease,—Klebs* accidentally induced the disease in a dog by feeding it with the milk of a cow in the last stages of phthisis. The use of this milk seems always to produce tuberculosis, which commences as an intestinal catarrh, and then gives rise to mesenteric glandular tubercles; later it affects the liver and spleen, and finally the thoracic organs. He thinks it probable that the virus of tuberculosis may exist in varying proportions in the milk of phthisical cows according to the extent of the disease in them; and he further believes that the malady may be developed in children born without any tendency to it, through the medium of the milk of the mother or nurse.

Böllinger thinks it probable that intestinal tubercu-

losis, consecutive to pulmonary phthisis, may be produced by the sputa being swallowed and passing into the intestine.

The present status of the transmissibility of tuberculosis is admirably summarized in Gerlach's statement of the results of his experiments. 1. The tuberculosis of cattle is very infectious. 2. The tubercles covering the serous membranes, as well as those in the other organs, are as infective, and produce the same tubercles, as the tuberculous matter of the lungs. The identity of pulmonary phthisis of cattle and general tuberculosis cannot be doubted. 3. Infection can be produced after inoculation as well as after ingestion of the tuberculous matter. 4. The *flesh* of animals affected with tuberculosis possesses, in certain conditions, the power of infecting, though to a less degree than tuberculous matter. 5. The temperature of boiling water destroys the infective principle, though boiled tubercles, nevertheless, often preserve a certain degree of virulence. It is in this as in trichinosis. 6. The infective properties of uncooked phthisical milk can no longer be doubted or denied.

Thorough cooking of the milk and flesh, it is true, may completely destroy their virulent properties; and even though flesh in itself is hardly to be regarded as contaminating unless it contains infiltrated lymphatic glands, yet, as we all know that tubercularized viscera, when they are not much affected, are not rejected as food, we must, in the light of all these experiments, regard these articles as playing an important part in the propagation of tuberculosis in the human species. To enumerate here the prophylactics against such possible sources of contamination would be superfluous; but does it not behoove our sanitarians and legislators to adopt the necessary preventive measures?

Another form in which infectious phthisical matter may enter the economy through the digestive system is that of the sputa, either in the moist or dried condition. Veterinarians have long believed and admitted this source of infection among cattle. That the dried mucosities and secretions are capable of transmitting the disease among animals scarcely needs any further proof than the evidence already furnished. Upon this point the observations of M. Grad are very conclusive. When visiting the stables of an extensive farmer at Leinheim, he was informed that every year for five years one of the cattle had died from phthisis; "and, what is very curious," said the farmer, "this always happens in the same stall." Believing that an hereditary tendency was doubtless the efficient cause in this succession of losses, another perfectly healthy animal was placed in the same stall, which in time presented all the evidences of the disease. The conclusion being now made that, in all probability, the disease had been transmitted by the ingestion of the matters expectorated by the animals which had previously inhabited the same place, all the wood-work of the stall, manger, and rack was removed, and the place thoroughly disinfected. It is significant that, although the stall was rebuilt and successively occupied, tuberculosis made no more victims in it.

* Klebs, "Ueber die Entstehung der Tuberculose und ihre Verbreitung in Körper," Virchow's Archiv, Bd. xlv. S. 242.

So great is the danger of transmission of tuberculosis among cattle that it is considered advisable to isolate completely those that are diseased from the healthy animals. For ourselves, we do not understand how, in the face of all these facts, it can any longer be said that the human species are exempt from these same dangers of infection.

R. M. B.

CORRESPONDENCE.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

NEW YORK, November 25, 1874.

THE meeting of the Medical Society of the County of New York last evening was one of unusual interest. The retiring President, Dr. Elsworth Eliot, gave a brief valedictory address, in which he alluded to the history and progress of the Society during the past year, referred in an appropriate manner to those who had been retired from the ranks of membership by death, and gave a stinging rebuke to that class of regular physicians who make known their business and qualifications to the people at large by means of advertisements in the newspapers,—one of whom had been ignominiously and promptly expelled during the year. He also referred to the fact that while certain medical societies in the city—he mentioned the Medical and Journal Association—were in the habit of inviting members of the daily press to be present, so that reports of their proceedings were frequently found in the newspapers the next morning, this practice did not hold good in regard to this Society.

He touched upon the question of the medical law of this State, as passed by the Legislature at its last session, which compels every medical graduate in this city to register, and every man or woman practising medicine in this city who does not hold a diploma, to pass an examination before a properly appointed examining board.

While the law does not cover the ground so fully as it is wished, yet, if the community by its enforcement are the gainers, it will not have been passed in vain. The censors have exercised the utmost vigilance; and they are not disposed to let down the bars so that designing men can claim equality in rank with the regularly qualified physician. He adverted to the action of the Board of Public Charities and Corrections, and thought that the rule granting equal clinical advantages in hospitals to the several medical schools would work to the advantage of medical education and the community at large. Dr. Eliot did not favor the practice of giving to specialists a particular designation,—as, for instance, to him who practises exclusively upon the eye, the name oculist. He preferred and recommended the manner of designation as follows: "Geo. Blank, M.D.; special attention given to Diseases of the Ear," etc.

The term "Doctor," in medicine, should apply to all graduates. The variation should consist in something after the above form.

Dr. Eliot then retired from the chair, and Dr. Sands, the President-elect, assumed control as presiding officer for the ensuing year; and, in doing so, he called attention to an invitation to the members of this Society to meet the Academy of Medicine to consider the subject of the erection of a building to be devoted especially to the meetings of the societies of the city,—or, in other words, the founding of a home for the profession in this city.

Prof. Sands then proceeded to deliver his inaugural address, the principal object of which was the consideration of Esmarch's method of bloodless operation, and the results of the same as regards the city of New York and vicinity during the last year.

He first considered briefly the history of the operation; secondly, its advantages and disadvantages; and thirdly, an estimate of the value of the operation according to the experience of our own surgeons. He also described the method of the application of the bandage. He prefers an elastic bandage to the cord, because the latter will be apt to injure the vessels and nerves, while the former, on account of the surface over which the pressure is extended, is less liable to this result.

As regards the operation in this city, Prof. Sands presented a table of cases collected from the principal hospitals of New York, Brooklyn, and Jersey City, and from the private practice of Drs. Wood, Krackowizer, Gouley, Ely, Weber, Little, and himself. The records of the Charity Hospital are not included, as they were so imperfectly kept that no use could be made of them. He also failed to obtain the experience of St. Francis's Hospital, in this city, where more than twenty bloodless operations are said to have been performed. He had endeavored to procure all of the hospital cases, both good and bad; and, although some of the histories are imperfect, they present many interesting and instructive details. The list embraces one hundred and forty-three cases, including 63 amputations, excluding those of the fingers and toes. Of these operations 44 were primary, for injuries, and 19 secondary, or for disease. Of the primary amputations 10 cases, or 22.7 per cent., terminated fatally, the causes of death being as follows: pyæmia, 4; exhaustion or shock, 3; spreading gangrene, 1; hemorrhage, 1; erysipelas, 1. Of the cases fatal from pyæmia, one patient had the disease at the time of the operation. Of 8 cases of primary amputation of the thigh, 2, or 25 per cent., ended fatally. Of 11 cases of primary amputation of the leg, 3 cases, or 27.3 per cent., were fatal.

Secondary amputations—19 cases—give us a mortality of 21 per cent. The causes of death are stated as follows: tetanus (existing at time of operation), 1; exhaustion, 1; phthisis, 1; pyæmia, 1: total, 4.

Although he had not the means of making an exact comparison, he believed that the percentage of recoveries in these primary amputations—which were nearly all performed upon hospital patients—is somewhat larger than is commonly observed in such operations.

Of sixteen cases of excision of the joints, only one

proved fatal, the cause of death being pyæmia; another case will probably end fatally, however, as when last heard from the patient was reported to have tetanus. Finally, the list includes two more deaths: one following an operation for necrosis,—the only fatal case out of 36,—and the other an operation for ligation of the ulnar artery, performed for a wound near the wrist.

Upon the whole, the method is one concerning which he spoke in the highest terms. It is one of the most valuable surgical expedients of modern times, and needs only proper knowledge and skill in its application.

Prof. James R. Wood, M.D., remarked that he had operated twenty-five times, each time employing this method, without bad results, with the exception of one case, mentioned in the table of Dr. Sands. He has repeatedly operated, both in hospital and private practice, in young and old, men and women, and has had no trouble whatever, and he has "fallen in love with the operation." The surgeon who formerly performed his operations by groping in the darkness can now witness each step of the operation with the eye. "Is there not," said he, "something beautiful in this,—something worthy the attention of surgeons?" He was not in favor of the cord, but of the bandage.

Prof. Frank H. Hamilton has made eight operations employing the bloodless method,—four amputations and four exsections,—and he is highly pleased with the success attained. He has had no accident that he can possibly attribute to Esmarch's method. He did not look upon the cord with favor. He preferred a bandage.

Prof. Markoe was satisfied with the efficacy of the method in preventing hemorrhage. He has had no accidents from this cause. He mentioned a case where the cord had been used. There was no sloughing at the time, but five or six weeks after the operation, just at the point where the cord had made pressure, a sloughing occurred down or nearly down to the bone. The case, however, recovered. With this single exception, he had experienced no bad results.

Dr. Krackowizer, who was the first to employ this method in this city, on the 22d of October, 1873, is still in favor of it. Instead of the rope or elastic webbing or bandage, which is objectionable on account of the possibility of its accumulating filth, and because of the inability of the surgeon always to secure the most approved articles, he thought it well to extemporize a bandage whenever practicable. He had from the first objected to the cord, and was in the habit of splitting a common india-rubber hose, an inch or so in diameter. This served the principle and the purpose.

Dr. Watson spoke of a case occurring in the town of Niagara, N.Y. The wrist was crushed. Operation was performed at the lower third of the fore-arm, by Esmarch's method. On the second day after the operation, the tissues became somewhat discolored. On the fourth day the limb in the neighborhood of the stump became gangrenous. The unfavorable character of the case rendered a second operation necessary. He has not heard further from the case.

Dr. Parker had not had any personal experience in

the matter, but suggested in a general way various untoward results which might possibly happen.

To sum up, the sentiment of the meeting appeared to be largely in favor of this method. It was looked upon as second in importance, as relates to the whole field of surgery, to the discovery of anæsthesia; and, like the subject of anæsthetics, it requires close and extended study to bring it to a state of perfection. W.

REVIEWS AND BOOK NOTICES.

THERAPEUTICS AND MATERIA MEDICA. By ALFRED STILLÉ, M.D. Fourth Edition, thoroughly Revised and Enlarged. H. C. Lea, Philadelphia, 1874.

The magnificent work of Prof. Stillé is known wherever the English language is read and the art of medicine cultivated,—known so well that no encomiums of ours could brighten its fame, and no unfavorable criticism could tarnish its reputation. Its peculiar merits and its peculiar faults—the individuality of the book, so to speak—have long since been generally recognized, so that it is our only duty to announce the appearance of this new edition, and to assure our readers that it is, as it were, an exaggeration, or an intensification—pardon the word—and amplification of the familiar volumes. So much more has been gathered into this vast storehouse of the universal clinical observation that the reader will be more embarrassed than ever by the very mass of matter. Two hundred and fifty new pages indicate the amount of this addition.

We are very far from desiring to criticise the volumes before us. As an American we are proud of them, and as a Philadelphian we are doubly so, but we cannot refrain from making a few remarks upon a paragraph in their preface.

Dr. Stillé says that in the first edition of the work he contended against "the mischievous error of seeking to deduce the therapeutical use of medicines from their physiological action. Continued study, observation, and reflection have tended to strengthen his convictions upon this subject, and to confirm him in the faith that clinical experience is the only true and safe test of the virtues of medicines." We are not exactly sure of the meaning which Dr. Stillé intends to convey by these words. If he means simply that clinical experience guided by a thorough knowledge of the physiological action of remedies and of the pointings of nature in disease is the ultimate test in therapeutics, we know of no one who will disagree with him. But if he means that therapeutics is to be advanced solely or chiefly by what we may be pardoned for calling the blind, unlettered experience of mere clinicians, who are not acquainted with the physiological action of remedies, and even despise such knowledge, we most earnestly dissent. If there be no better method of therapeutic inquiry than that so long employed, the future looks to us almost hopeless, and we welcome the quiet calm of that therapeutic despair—the so-called expectant method of treating diseases—in which patients are left to the sole care of nature and of hygiene. The work of Prof. Stillé itself—we speak with the utmost respect—seems to us to afford the strongest evidence of the utter failure of purely clinical therapeutics. How any one can look over the index of "Therapeutics" and see the long list of the most diverse medicines used in various individual diseases, and still retain his faith, is more than we can understand. Thus, in rheumatism there are between forty and fifty more or less antagonistic remedies. Or, as it may be objected that rheumatism is very variable in its type, let us examine tetanus,—of all

diseases the most constant in its causation, its type, and its symptoms. All of the substances referred to in the index are mentioned in the text as having been found useful in the experience of some one; on very few of them does Dr. Stillé give any opinion based upon personal experience, and, indeed, very frequently he abstains from expressing any opinion whatever. This is, then, the index list: calabar bean, strychnia, aconite, alcohol, cold, heat, nitrite of amyl, wine, tobacco, ether, garlic, belladonna, tartar emetic, chloral, cannabis indica, quinine, colchicum, chloroform, electricity, bromide of potassium, and opium, besides counter-irritation with various substances. In other words, the greater part of the official strongest arterial stimulants and the strongest arterial sedatives, of the strongest spinal sedatives and the strongest spinal stimulants, the adding to the system and the taking from the system of the diverse forces of nature, nearly all of the official drugs which most profoundly affect the sensorium, the most virulent antagonistic poisons and the most trifling of drugs, all are recommended by experience for the cure of tetanus! Verily, the profession must be worse than a blind man led by the blind, if it does not begin to doubt this infallible guide,—experience. If eighteen hundred years of labor have only this to offer as their fruit, is it not time that we should mistrust the method?

ERYSIPELAS AND CHILD-BED FEVER. By THOMAS C. MINOR, M.D. Robert Clark, Cincinnati.

The perplexing subject of puerperal fever ever and anon attracts a new writer, who is fortunate if he flutter away again with unsung wings. The little volume before us—one of the latest contributions to the literature of this disease—is an examination of American statistics, aiming to discover what connection, if any, exists between puerperal fever and erysipelas. To many this immediate question seems already decided, and yet all are conscious that about this fever there is a mystery still unsolved. The evidence seems conclusive enough that a disease, called in the mortuary reports of cities and in the statistics of hospitals puerperal fever, is prone to coexist with another disease called erysipelas; but until the varied forms which are comprehended under these names are strictly described, analyzed, and made distinguishable by the average professional mind, the matter will be likely to remain in its present unsatisfactory state. While some observers contend that all cases of child-bed fever are cases of septicæmia, others as decidedly deny it, and argue for the existence of a distinct specific contagious and infectious principle, as distinct as that supposed to exist in the case of typhus and scarlatina; while some levellers would merge all contagions into one universal destructive agent, which, modified by circumstances, produces scarlatina, typhus, erysipelas, etc., at its own sweet will.

Dr. Fordyce Barker, in his recent admirable work on "The Puerperal Diseases," states his belief in a puerperal septicæmia, scarlatina, erysipelas, etc., as distinct and different from true puerperal fever itself,—a disease which he claims to have seen and recognized before labor, in cases where septic infection was impossible; epidemic causes, contagion and infection, producing the true disease; autogenetic infection and direct inoculation or nosocomial malaria, its spurious but equally deadly ally, puerperal septicæmia. The statistics collected by Dr. Minor embrace those of the various States and Territories—in fact, all the statistics of all the States accessible—for all the years recorded,—public statistics in our favored land being as yet in their infancy,—with as many accompanying conditions—elevation, temperature, humidity, season—as possible.

The work, it will be seen, therefore, is one of great value for reference, though the general conclusion reached by the author is guarded, and such as might be

expected, viz., that "erysipelas and puerperal fever seem to prevail together throughout all the States." The author says, in conclusion, that he has at least "the satisfaction of knowing that many pleasant hours have been whiled away in the attempt to throw light on a somewhat obscure point."

GLEANINGS FROM OUR EXCHANGES.

DOLBEAU'S OPERATION FOR STONE IN THE BLADDER—PERINEAL LITHOTRITY (*The Lancet*, October 17, 1874).—Mr. William Ewart calls attention to an operation for the extraction of vesical calculi, which, though really a revival of the old Marian method of "small incision, much dilatation," is also a great improvement upon it, inasmuch as the passage which previously resulted from the laceration of the tissues is now formed by their simple and equable compression. The stone is almost always crushed previous to its removal, whence the name of "perineal lithotritry" given to the operation.

The instruments used are few: a scalpel, a screw dilator, a crushing forceps, and various-sized seizing forceps. The essential feature in the screw dilator is that the blades keep parallel in every stage of their expansion, forming together a cylindrical body, the diameter of which varies with the action of the screw. At rest, the six smooth blades or columns are in apposition, and run up to a common point. They conceal two balls capable of moving up and down along a central stem, and of separating the columns more or less without causing them to diverge. The expanding portion of the instrument measures eight centimetres in length, one and one-fifth centimetres in its smallest diameter, and two centimetres in its largest; the limit of distensibility of the neck corresponding to a diameter of two and two-fifths centimetres. The forceps are of great power, and are so constructed that they can be opened after their insertion without any divergence of their limbs taking place in the thickness of the perineum.

The patient is placed in the usual lithotomy position. The lower limbs are intrusted to two assistants; a third (whose office is responsible) takes charge of the strongly-bent and deeply-grooved staff; his duty is to keep it strictly in the middle line, to make its curve project in the perineum, and later to resist the pressure of the point of the dilator. The incision, two centimetres in length, is made with the blade upwards, and begins immediately in front of the anus, at the brown zone marking the passage of skin into mucous membrane. A deeper incision opens up the perineal fascia, through which the knife, guided by the left index-finger, is thrust into the membranous portion of the urethra. The work of dilatation now begins; and upon the amount of care with which it is accomplished depends in a great measure the success of the operation. Four successive dilatations are employed by Professor Dolbeau. The first stretches the external aperture and subcutaneous tissues. The instrument is next closed, and passed up to the groove of the staff and firmly pressed against it whilst the expanding screw is being turned,—a proceeding that causes the whole of the membranous portion to slit up along the line of incision. The instrument can now be pushed one step farther along the staff, which the assistant slightly depresses. As soon as the membranous region has sufficiently yielded to this third dilatation, the dilator is closed and pushed onward into the neck of the bladder, the staff is withdrawn, and the screw cautiously turned until expansion is complete. The passage thus formed is of uniform calibre, and has smooth walls. This can be felt by the

finger in the dead subject. In the living, Prof. Dolbeau deprecates the use of digital examination. The stone is now within easy reach, and if very small will be removed by the light forceps used in making the first exploration after removal of the dilator; generally, however, it has to be broken up by the *casse-pierre*. This is introduced without any great difficulty, and, thanks to the broad blunt beak in which it terminates, it obtains an easy grip even of the harder and smoother concretions. Large stones cannot be clasped, but will usually yield to the repeated bites of the instrument. The fragmentation of the stone is often very great; and to extract everything, even with the help of injections, is a task requiring much patience. Before the patient is released from the lithotomy posture, a catheter is always introduced through the natural channel to obtain a crucial proof of the bladder having been cleared. The loss of blood is trifling, and seldom exceeds two or three teaspoonfuls; the wound is minute:—two important considerations in dealing with old age and albuminuria. The bulb is out of the way of danger, and the rectum is not seriously imperilled. The grave surgical complications of pyæmia and of urinary infiltration have been hitherto unknown.*

The patients are generally enabled to leave their beds soon after the operation, often as early as the second or third day.

The operation itself is, however, a long one; it must be conducted slowly to be safe, and of course this necessitates a prolongation of the anæsthesia. It is also difficult, and requires to be studied in all its details, and practised repeatedly, before it can be safely attempted.

NOTES AND QUERIES.

GEORGE LABAR, THE POST-CENTENARIAN.

WE briefly chronicled, yesterday, the death of George Labar, of Monroe County, Pennsylvania, which occurred on Saturday last. It was the close of one of those wonderfully prolonged lives which run far back beyond the memory of other living men. George Labar was born in the autumn of 1763, one hundred and eleven years ago, at Mount Bethel, Northampton County, now called Portland, where his baptismal register still exists. He was of French descent, his grandfather settling in Pennsylvania in 1730, a fugitive from religious persecution.

He spent his whole long life among the scenes of his nativity, and retained to the last vivid recollections of the old Indian wars, the Revolution, and the subsequent early events of American history. Nearly seventy years ago he accompanied his parents in their emigration to Ohio, but only remained with them a few days, and returned home. His father lost his wife when he was ninety-eight years old, and the gay old gentleman married again at one hundred! He died at one hundred and five, and was buried in Ohio.

George Labar, who has just died, has preserved a wonderfully hale and hearty condition to the last. He was of medium height, had a large head, well covered with snow-white hair, a keen, quick eye, and a face of strongly-marked features, not much marred by age. In walking, he stooped considerably, but was possessed of sufficient vigor to walk some rods without assistance. Like all centenarians, he remembered General Washington,—in this case there is no improbability in the narration,—and talked enthusiastically over the time when the news of Washington's capture of the Hessians at Princeton spread up the valleys and brought joy to so many loyal hearts. He thought Washington had a charmed existence, and that bullets were powerless to harm him. Once he saw the great general at Easton, then an insignificant hamlet, and he said Washington wore buckskin breeches, silk stockings, and silver shoe-buckles. This aged relic of a former century related these particulars with a zest and earnestness which strongly persuaded one of their truthfulness.

George Labar had never been sick but three times in his life: once with yellow fever, once with camp-fever, and once with typhoid fever. He

used tobacco very freely all his life, both smoking and chewing, but was very moderate in his use of liquors of all kinds. He took daily exercise in the woods, among which he had grown up, felling trees and chopping railroad-ties up to within the last two or three years. It is recorded of him that in 1869, when one hundred and seven years old, he felled trees and peeled three wagon-loads of bark, which one of his youngest sons, a young chap of sixty, hauled to market for him.

George Labar was married in 1788, and leaves a large number of descendants, who are scattered around Monroe County. His oldest son was born in 1791, and married, at twenty-one, a girl of thirteen! Their oldest child is now sixty, and is only fifteen years younger than his mother. In 1870, George Labar had living a sister aged eighty-six, another sister aged ninety-two, and a brother, in Canada, aged ninety-eight, a brisk old boy, who paid George a visit in 1868.

One of the most remarkable features of Labar's longevity is the fact that he voted for General Washington for President, and has voted at every Presidential election since, and *always for the Democratic candidate!* And yet he lived to be one hundred and twelve years old.

George Labar was one of the best-attested cases of extreme longevity on record, and, while his extraordinary prolongation of life attests the value of a good constitution lived out in a rugged experience of out-door life, it presents quite a serious difficulty in the way of the absolute doctrine of the anti-tobacco and whisky theory.—*Philadelphia Evening Bulletin*, October 1.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM DECEMBER 1 TO DECEMBER 7, 1874, INCLUSIVE.

- STERNBERG, G. M., ASSISTANT-SURGEON.—Granted leave of absence for one month. S. O. 196, Department of the Gulf, Dec. 1, 1874.
GIBSON, J. R., ASSISTANT-SURGEON.—Granted leave of absence for fifteen days, upon completion of his examination for promotion. S. O. 260, A. G. O., Nov. 30, 1874.
PHILLIPS, H. J., ASSISTANT-SURGEON.—Assigned to duty at Fort Ontario, Oswego, New York. S. O. 236, Military Division of the Atlantic, Nov. 30, 1874.
HEIZMANN, C. L., ASSISTANT-SURGEON.—Relieved from duty in the Department of the Platte, to report in person to the President of the Army Medical Board, New York City, for examination for promotion, and, upon its completion, by letter to the Surgeon-General. S. O. 260, A. G. O., Nov. 30, 1874.

By S. O. 260, War Department, November 30, 1874, the following-named Assistant-Surgeons (recently appointed) are directed to report as follows for assignment to duty:

- WINNE, CHARLES K., in person to the Commanding General, Department of the Platte.
AINSWORTH, F. C., in person to the Superintendent United States Military Academy, West Point, New York, for temporary duty.
HAVARD, VALERY, by letter to the Commanding General, Department of Dakota.
HOFF, JOHN VAN R., by letter to the Commanding General, Department of the Platte.
PAULING, H. OFFLEY, in person to the Commanding General, Department of Dakota.
ADAIR, GEORGE W., in person to the Commanding Officer, Newport Barracks, Kentucky, for temporary duty.
BROWN, PAUL R., by letter to the Commanding General, Military Division of the Atlantic.
MOSELEY, EDWARD B., by letter to the Commanding General, Department of the South.
JACKSON, DONALD, in person to the Commanding General, Department of Texas.
SEMIG, BERNARD G., by letter to the Commanding General, Department of California.
SKINNER, JOHN O., in person to the Commanding General, Department of the Columbia.
FINLEY, JAMES A., in person to the Commanding Officer, Fort Monroe, Virginia.
DE LOFFRE, AUGUSTUS A., in person to the Commanding General, Department of the Missouri.
BEDAL, SYLVESTER S., by letter to the Commanding General, Military Division of the Atlantic.
HAMILTON, JOHN B., in person to the Superintendent of Mounted Recruiting Service, St. Louis Barracks, Missouri, for temporary duty.
WILCOX, TIMOTHY E., in person to the Commanding General, Department of the Missouri.
MAUS, LOUIS M., by letter to the Commanding General, Department of the South.

* In none of Prof. Dolbeau's cases did the prostate resent the pressure to which its tissues had been subjected; and the neck of the bladder always escaped rupture or over-stretching of its fibres.

MOSELEY, E. B., ASSISTANT-SURGEON.—Assigned to duty at Columbia, South Carolina. S. O. 197, Department of the South, December 4, 1874.

SATURDAY, DECEMBER 19, 1874.

ORIGINAL COMMUNICATIONS.

EXCISION OF THE HIP-JOINT IN CHRONIC ARTHRITIS OR HIP-DISEASE.

WITH ANALYSIS OF SEVEN CASES OF THE OPERATION.

BY H. LENOX HODGE, M.D.,

Surgeon to the Children's Hospital, Surgeon to the Presbyterian Hospital, etc.

IN preparing a paper for the Philadelphia County Medical Society, I have chosen the subject of Excision of the Hip-Joint in Cases of Chronic Arthritis or Hip-Disease, because I believe it to be a matter of great importance, and one concerning the value of which there has been, and still is, a very different estimate formed by different surgeons. I take pleasure, therefore, in contributing my share towards the practical study of this operation. I have excised the hip-joint for disease seven times, and an analysis of these cases will form the basis of this paper.

Case I.—Clinton L., 4 years of age, was admitted into the Children's Hospital, December 1, 1869, on account of hip-disease of the right hip. The disease had existed for about one year; during seven months of this time he had been under treatment at the Pennsylvania Hospital. After admission into the Children's Hospital he improved for a while, but in November, 1870, he was obliged to return to bed on account of an abscess forming in the upper part of the thigh. While out of bed he had worn an apparatus to keep up extension and counter-extension upon the limb, and while in bed extension was made by means of a weight and pulley. After the formation of the abscess, his health failed very much, and during December and January he was much prostrated by persistent diarrhœa. It was determined, therefore, to make an effort to save his life and remove the disease by an excision of the hip-joint. The operation was done January 28, 1871, by a single incision behind the trochanter in the line of the limb, slightly curved around the trochanter. The head and neck of the femur were easily separated from their attachments, raised from their position, and removed below the trochanters by means of a saw carried below the bone, and some diseased portions of bone were removed from the acetabulum by a gouge. The wound was closed by sutures, dressed with sweet oil, and extension made to the limb by adhesive plaster with weight and pulley. The operation was followed by no ill effects: he had no unfavorable symptoms, and began at once to improve. The diarrhœa ceased, and, as the wound granulated and closed, he gained health and strength. After he left the bed he grew stout and robust. He walked well without crutch or cane, wearing a shoe with the sole and heel thickened about three-quarters of an inch more than the other. He engaged in active sports with the other children, and while playing "tag" would not hesitate to escape the pursuit by climbing into the basement-window. He was discharged well, with the wound closed and the cicatrix well hardened, in October, 1871.

Case II.—Elizabeth S., 5 years of age, was admitted into the Children's Hospital, February 18, 1871, suffering from hip-disease of the left hip-joint, and with a large and painful abscess on the inner side of the thigh. The disease had existed for about two years, and was

believed to have followed a fall from a crib. Since that time she had complained chiefly of pain in the knee. The abscess was opened upon the day of admission, and was followed by temporary relief. Her health, however, soon began to fail very rapidly, and about the beginning of May two other abscesses began to approach the surface. One of these was situated on the outer side of the thigh, and the other pointed above Poupart's ligament. Diarrhœa also attacked the little patient, and she became much emaciated and exhausted. She was so much reduced by these causes, and had such marked hectic fever, that it was thought she could live but a very short time. The abscess above Poupart's ligament opened during the night of May 19. It had been resolved to give her a chance for life by excising the hip-joint, and the operation was done May 20, 1871. Not only was the femur diseased, but the acetabulum and rami of pubes and ischium were involved. Portions of each of these bones were removed, and the denuded surface scraped by the gouge and chisel; the section of the femur was made below the trochanters. The abscess which pointed and discharged above Poupart's ligament was found to communicate with the one in the thigh by an opening through the membrane of the obturator foramen of the innominate bone. A twisted cord of oakum was passed through the wound made for the excision, then carried through the obturator foramen and along the sinus to the opening made by the abscess on the abdomen above Poupart's ligament. This seton was allowed to remain, in order to drain away the discharges. Sutures were inserted to bring the edges of the wound together, olive oil was applied as a dressing, and extension was made by weight and pulley.

The patient, though in such a weak condition, was not depressed by the operation, but soon began to improve. The hectic fever and the diarrhœa gradually lessened and disappeared. The wound granulated and in great part healed. The child was able to sit up in a chair, and gained strength, flesh, and appetite. Her life was undoubtedly much prolonged, and a great amount of freedom from pain was derived from the operation. About seven months after the operation, the liver began to enlarge from amyloid degeneration, which continued steadily to increase. Diarrhœa returned, and at times was very persistent. She emaciated exceedingly, and on the 6th of July, 1872, she died, nearly fourteen months after the operation.

Case III.—Lewis C., 6 years of age, was admitted into the Children's Hospital, September 13, 1870, on account of chronic arthritis of the left hip-joint. He was placed in bed and treated by extension, but abscesses formed and opened on the outer part of the thigh. The child gradually lost flesh and strength, and it was determined to excise the hip-joint. This was done on May 25, 1872, nearly two years after his admission to the hospital. The head of the femur was found out of the acetabulum, lying on the dorsum of the ilium. The head of the femur and the under surface of the neck were carious. The acetabulum was also somewhat ulcerated. The wound did well, and the condition of the patient improved. By the 12th of June the greater part of the wound had healed, but long sinuses and ulcerations from the old abscesses still remained, and required incisions with the knife at several different times. At the time of his discharge—July 24, 1874—he could walk the length of the ward without crutch or cane, but some of the sinuses were not yet healed, and he remained pale, with the abdomen distended from amyloid enlargement of the liver and accumulations of gas in the intestines. He is now living at Germantown, and occasionally reports at the hospital.

Case IV.—Catherine G., 6 years of age, suffering from chronic arthritis of the left hip-joint, was admitted into the Children's Hospital, May 10, 1871. A large abscess gradually formed on the outer side of the thigh and extended from the great trochanter to the lower third of the thigh. It did not cause pain, but contained a large amount of pus. The pus was removed by the aspirator, but gradually accumulated again, and discharged by an opening in the lower part of the thigh. The patient became greatly emaciated and hectic; diarrhoea began and continued, notwithstanding every effort was made to check it. In this most debilitated condition, excision of the hip-joint was made on June 29, 1872. The femur was sawn, as usual, just below the trochanter, but the bone was found so much softened that it was deemed advisable to remove another section of about half an inch. The acetabulum was found perforated by ulceration. The after-treatment was by means of simple dressings of oil, and by extension with weight and pulley. The operation was followed by no bad symptoms, but by gradual improvement in general health, until she recovered flesh and color. She is now quite stout, with a good healthy color. The wound healed perfectly, though slowly, on account of the great extent of the abscess and consequent sinuses. Once after the wound had closed an abscess formed, and it opened again. The limb is useful to her in walking with a thick sole to the shoe, notwithstanding the additional portion which was removed on account of the extension of the disease in the femur. As yet she prefers the use of the crutch, but is gaining confidence as well as ability to do without it.

Case V.—James M. was admitted to the Children's Hospital, March 27, 1872. He was then 10 years of age, thin and weak. His mother died from consumption. During the preceding winter he had complained of pain in his knee. Upon examination, he was found to have chronic arthritis of the left hip. He gave at first no account of any injury; but, upon questioning him closely, he said that one day at school some boys had thrown him down and jumped upon him. He was treated by extension and counter-extension to the limb, and was sent to the Seashore Hospital at Atlantic City during the summer, to give him the benefit of sea-air and bathing. But his general health gradually failed more and more, and it was thought advisable to excise the joint. This was done on May 14, 1873. There was dislocation of the femur on the dorsum of the ilium. Ulceration had nearly destroyed the head of the femur, and the under surface of the neck was carious. The anterior and inferior portions of the rim of the acetabulum were extensively diseased, having sharp edges and being bare of periosteum. The head and neck of the femur were removed below the trochanters, and the diseased portions of the acetabulum cut out by the gouge. The after-treatment was the same as in the other cases. He shows no signs of depression after the operation, nor any ill effects from it. The wound gradually granulated, and in great part closed. He was discharged from the hospital March 23, 1874. He is now living with his parents, and able to go out on errands for household wants. He takes his crutch for use on the street, but is able to walk without it in the house. His general health is good, and his appetite excellent, though he is still thin.

Case VI.—Louis M. has had disease of the hip since 1871, when he was 6 years of age. He lived in Easton, and was treated there by several physicians. At first he was confined to bed, and had splints applied for nine months. Then an apparatus was given to him, and he was allowed to walk about with it. He was finally brought to the Children's Hospital, and admitted June 6, 1873. The disease was then far advanced, and his general health much debilitated. Shortly after admission the hip-joint was excised, and portions of the

acetabulum removed, as well as the head and neck of the femur. The head and neck of the femur were almost entirely absorbed. All that remained of the head was a small nodule of cancellated structure. There were bands of cartilage binding the femur to the sides of the acetabulum, both on the inner and outer surfaces of the capsular ligament. The operation was very well borne. The wound has not yet entirely closed; there are two deep sinuses, with considerable swelling, indicating that there is caries still existing. He moves about the ward rapidly with a crutch, and can walk for a short distance without using it. He has been allowed to go to Atlantic City, and also to his home in Easton on a visit.

Case VII.—Daniel C., 7 years of age, was admitted into the Children's Hospital, April 22, 1874, on account of chronic arthritis of the right hip. He was very pale and emaciated. About four months previously he had received a fall, but was able to walk about during that day. The next day he complained of pain in the knee and hip, and was obliged to remain in bed. He was treated by extension with a weight. An abscess formed and discharged behind the trochanter. The limb became shortened, with very marked inclination of the pelvis. The knee was found, when he was admitted to the hospital, partially ankylosed, but there was a remarkable degree of motion at the hip. On account of the great impairment of his health, it was thought advisable to remove the diseased bone without unnecessary delay. Excision of the hip-joint was therefore done May 6, 1874. The head of the femur was found entirely separated by ulceration, and lying by itself in a pocket in the gluteal muscles, above the great trochanter. The acetabulum was occupied by the extremity of the neck of the femur, and was in good condition except at the lower part of its rim. The femur was divided below the trochanters, and the diseased portion of the acetabulum carefully cut away. The after-treatment was conducted upon the same principles as in the other cases. The patient reacted well after the operation. His pulse—already weak and frequent before the operation—became more rapid. His temperature two days before the operation was as high as 102°. The next day it was 101°, and the day of the operation 99°. The following day it went up to 104°, then gradually declined until it ranged a little above or below 100°, until May 12, six days after the operation, when the temperature increased to 105°. At the same time an erysipelatous inflammation showed itself at the wound, and extended both down the limb and up on the abdomen, and to the genital organs, with marked distention of the scrotum. The temperature declined, the respiration became difficult, vomiting began, and the patient died from exhaustion, May 17, on the twelfth day after the operation. This case is of special interest as being the only one, so far as I know, of erysipelas occurring in our Children's Hospital; and also the only one in the practice of the house, under the care of either Dr. Ashhurst or myself, in which a fatal result has been directly or indirectly the immediate consequence of excision of the hip-joint. The weather after the operation was cold and moist, and the erysipelas appears to have been due, in part, to unusual atmospheric changes.

The first point to which I would direct your attention in our study of these cases is *the cause of hip-disease*. Is it a constitutional disease, or is it due to inflammation resulting from injury? In one of the cases (VII.) the pain and inflammation followed so quickly after a fall as to leave no room for doubt that the injury was the direct and positive cause. In each of the other cases no one injury was distinctly present to the mind of the patient or

the friends as the cause of the disease. But, upon inquiry, some fall, blow, or other injury could almost always be recalled as having occurred at or about the time of the beginning of pain. This coincides with my experience in numerous other cases of hip-disease not operated upon. A slight injury appears to be followed by very destructive results. This would show a predisposition to the disease, and has led many to suppose that the disorder is constitutional in its origin. The question has been earnestly debated whether hip-joint disease is or is not due to tuberculosis or struma. In the cases before us there does not seem to have been any marked hereditary tendency. But few of the parents were consumptive; generally the other children of the family were healthy, and in none of the cases did the child affected give any other evidence of constitutional disease. In none of the cases was syphilis known to be the direct or indirect cause. It is true that this subject is a difficult one for investigation, and that syphilis exists frequently when unsuspected, and that it is a disorder occurring often in hospital practice. Yet the history of these cases shows that for a number of years after birth the children appeared healthy, without any of the evidences of congenital syphilis, and that the fathers, mothers, and children of the same family exhibited no signs of syphilis. In my opinion, therefore, the disorder is generally, if not always, of traumatic origin, but occurs far more readily in those children who are weak and delicate, whether from some constitutional disease or not. This predisposition may be inherited, or induced by poor food, bad air, or attacks of various acute disorders, which impair the health and vitality of the child.

Various names have been applied to this chronic inflammation of the hip, which originally, at least, indicated some theory in relation to the disorder, such as strumous disease of the hip, morbus coxarius, hip-disease, coxalgia, and arthritis of the hip-joint.

The next point of importance is in reference to the *pathological changes* which take place in the structures of the joint and the surrounding tissues. In all of our cases an abscess had formed, and in each of them this abscess communicated with the interior of the joint. Generally these abscesses discharged upon the thigh; but in one case, besides opening on the thigh, the pus had travelled through the obturator foramen, and, rising up within the pelvis, had opened upon the abdomen above Poupart's ligament. In regard to the existence of an abscess entirely exterior to the joint, I have seen no positive case.

The capsular ligament was in every case ulcerated and destroyed to a greater or less extent. In parts it would be thickened by inflammatory action, and in one case (VI.) it was very much strengthened by means of cartilaginous bands, both on its inner and outer surfaces, which were firmly attached to the sides of the acetabulum. The periosteum was always much thickened, and on the neck of the femur separated to a greater or less extent from the bone. The round ligament was found in every case destroyed. The cartilages were more or less eroded over the

surface of the acetabulum, and over the head of the femur they were in great part destroyed or separated from the bone. The changes which take place in the bone will be best understood by an examination of the specimens which I have brought with me. The head and neck of the femur were carious, and even the shaft of the femur was much softened, so that the saw passed through it with very little resistance. The head of the bone was greatly reduced in size by ulceration and absorption, and appeared as a mere nodule. In one case (VII.) it was entirely separated from the neck at the line of the epiphysis, and found in a distant position. The neck of the femur was generally shortened, and its under surface more diseased than the upper. The acetabulum in most of these cases exhibited less disease than the femur, yet in every one was carious in one or more localities, and in Case IV. it was perforated. The effect of the ulceration and caries is to widen and enlarge the acetabulum. This allows the diminished head of the femur to be drawn higher up, and, with the shortening of the neck of the femur, accounts for the shortening of the limb in many cases. In two of our cases (III. and V.) there was complete dislocation on the dorsum of the ilium, and in another (VII.) the head of the femur, separated by ulceration, was out of the acetabulum, and the extremity of the neck pressed against the acetabulum in its place. The greater amount of destruction shown by the femur than by the acetabulum would lead us to believe that in these cases the inflammation began first in the femur. As the disease had in each case far advanced from the primary stage, no positive opinion could be formed whether the disorder had begun in the capsular ligament, the ligamentum teres, the cartilage, or the bone.

We will next consider how we can distinguish hip-joint disease from other disorders or injuries in the same locality or possessing some of the same symptoms, and then point out under what conditions or at what stage the operation is advisable.

The *diagnosis* of hip-disease is usually very easy, and especially so in the later stages. The pain frequently felt in the knee is only apt to mislead early in the progress of the disorder, before any question of operative interference is thought of. It sometimes happens, however, that there is arthritis of the knee and of the hip at the same time. The slightest examination will, in ordinary cases, show the rigidity, the deformity, and the pain upon attempted motion at the hip. From traumatic dislocation, the evidence from the history of the case will generally leave no doubt in the mind as to the diagnosis. Congenital dislocation or malformation of the articulation has deceived at times some careful observers. As, however, the child is usually in good health, the question of excision is not likely to be considered. This disorder is comparatively rare. I have myself seen only two cases. It is first noticed usually when the child begins to walk, and the lameness is for a long time on the increase. It is not until the femur finds a secure resting-place, and the surrounding structures become accommodated to the deformity, and the disproportionate

development of the two limbs ceases, that we can hope for an arrest of the increasing lameness. There is no pain at the hip or knee; there is no rigidity, but, on the contrary, increased mobility. There is shortening, but by extension it can be at once completely overcome. The gait is peculiar, the pelvis yields to the affected side, the movements are quick, free, and without pain. If the child is placed upon a chair, it will jump upon the floor as fearlessly as a well child, and will make no effort to save the limb from the jar.

The cases which are most like to hip-disease in the later stages are those in which there is caries of the sacrum or innominate bone, with an abscess pointing in the region of the hip. I have charge at the present time of a little girl who has caries of the lower lumbar vertebræ and of the sacrum. She has had repeated abscesses, and some of these have opened on the buttock close to the hip; in others, the pus has travelled nearly to the middle of the thigh; and twice an abscess has formed and pointed on the inner side of the thigh close to the pubes. In this case there is great rigidity of the limbs, and one of them is strongly flexed and greatly abducted. In such a case as this, an examination, carefully made, of the joint by manipulation while the patient is under the influence of ether or chloroform, will show that the hip-joint remains unaffected.

In caries of the spine with a psoas abscess there is also a condition of affairs which simulates hip-disease. An inspection of the spine, combined with an examination of the hip-joint while the patient is under the influence of ether, will make plain the true location of the disease.

There is another injury which may be mistaken for hip-disease, and therefore we will allude to it, although it is extremely rare in childhood: namely, fracture of the neck of the femur. Such a case as that in our series marked VII. might be confounded with, and, indeed, was mistaken for, a fracture of the neck of the femur by the practitioner who first saw the case. The head of the bone had been separated by ulceration, and therefore the symptoms resembled somewhat those in which the neck of the bone is broken by injury. There was shortening, increased mobility, and no rigidity. But the history of the case showed that he had walked for a day after the reception of the injury; this, with the gradual formation of an abscess, the impairment of the general health, and the symptoms persisting and increasing long after what would have been the case if the bone had simply been broken by a fall, made it plain that the case was one of hip-disease.

In order rightly to estimate the true *value of excision of the hip-joint*, we should keep in mind the result of the disease if left to the best medical and surgical treatment without operation. In the early stages, almost every case can be greatly benefited or cured. In order to accomplish this, a long time will usually be required, and much care must be exercised, not only on the part of the practitioner, but also by the nurse and parent, in order to secure the fresh air, the good diet, and the proper adjust-

ment of the different forms of apparatus employed. But, as these cases ultimately get well, no question of operation is to be considered. In the later stages, however, when an abscess has formed and the bone has become carious, from prolonged suppuration visceral disease is apt to be induced, and there is great danger of the patient dying from exhaustion. Under favorable circumstances, children even at this stage may ultimately recover, and the limb may be of good service afterwards.

We have now under observation at the Children's Hospital a child of remarkable powers of constitution, who has passed through the different stages of hip-disease, including abscesses, and yet is in a fair way to recovery, even with motion at the hip, and is now in robust health. She has, indeed, been constantly under treatment for about five years. At one time her health seemed greatly to fail: diarrhœa set in, and persisted for several weeks. It was then decided in consultation that the operation would be necessary. She was, however, attacked with measles, and after this disorder had passed away her condition again improved, the diarrhœa ceased, and the suppuration diminished. The attack of measles, on account of the reaction which followed, seemed to have been of positive benefit to her.

In these later stages of hip-joint disease those who are of good constitution and strong may recover, but the weak and those of delicate constitutions, after a long and painful illness, will be likely to die. When the health begins to fail,—and we should not wait until too much ground is lost,—it becomes a serious question to determine what we shall do to save life; and the choice lies between *excision* and *amputation*. By excision we save a limb, which the above cases show may be of great service, and the operation, therefore, is much to be preferred to amputation, if not much more dangerous to life. In our seven cases only one death occurred shortly after the operation, and only one other more than a year after excision in a child who would probably have died in a few weeks if no operation had been done.

Dr. Sayre, of New York, writes to me that he has operated fifty times, and that the percentage of death before the wound closed is about twenty-five per cent. Or if we study the large number—three hundred and seventy-six*—collected by my friend Dr. Ashhurst, we find the percentage of mortality a little less than fifty per cent. The same authority has collected eight cases of amputation for hip-disease, and of these four died. Thus, so far as any inference can be drawn from statistics in which there is such disparity in the number of cases, the death-rate is about equal. Therefore, at the present day every one gives the preference to excision, as by it, without duly increasing the risk to life, we save the limb. In some exceptional cases, when the femur is diseased to a great extent in its shaft, amputation would be advisable. I have never seen a case to which it was applicable. Again, it may be at times necessary to amputate after unsuccessful incision. This, also, I have not had occasion to do or to recommend.

* This number does not include the seven cases described in this paper.

In studying the statistics of any operation, we should know not only how many died and how many lived, but also what was the condition of the patient prior to the operation, what was the cause of death, how long after the operation it occurred, and what was the condition of the patient as regards health and usefulness of limb in those who recovered. The percentage of success or of failure is very different, according as the operation is limited to favorable or to unfavorable cases.

In each of our seven cases we believed that death would result, after a painful illness, in a longer or shorter period, if no operation was done. In several of these cases death seemed imminent, and would have probably resulted in a few weeks without the operation. The cause of death in one case was erysipelas; and death occurred on the twelfth day after the operation. In the other case the cause of death was exhaustion, after prolonged discharge from a pelvic abscess, on the four hundred and eleventh day after the operation.

The condition of the patient's health in all who recovered after the operation was improved, and the limb more or less useful. In the case of Clinton L. (I.) there was everything that could be desired: the motion was perfect, and the muscular control of the leg complete; but it was necessarily shortened, and its mobility at the hip greater than natural. In some of the others there still remain sinuses and more or less evidences of inflammation which impair the usefulness of the limb. If these subside, the limb will become of greater value than reported above.

As regards the word recovery, we should not confound recovery from the effects of the operation with recovery from the disease. In the above cases all but one recovered from the operation, but it is still undecided how many will recover from the disease. One of those who recovered from the operation afterwards died of the progressive disease.

There is another comparison which we ought to make, and that is between the *value of the limb* left after excision when the cure is complete, and that left under similar circumstances when no operation has been done. The limb after excision is perhaps a little shorter than that after the natural cure, but it has greater mobility, with equal firmness and strength, and is therefore the better. In the case mentioned above, of natural cure, the mobility of the limb promises to be good; but generally there is more or less ankylosis. In the case of a gentleman whom I lately saw in my office, who had recovered from double hip-disease, from which he suffered in his childhood, there is so much ankylosis at the hips that, although he can walk quite rapidly, his gait is very peculiar, and consists in a rotary movement of the whole body, with flexion and extension at the knees and ankles, while the motion at the hips is hardly perceptible.

After excision, where does the extremity of the femur rest? In the majority of successful cases there is reason to believe that it is drawn against the acetabulum by the rectus muscle, chiefly by means of the tendon attached to the rim of the acetabulum.

After excision, does ankylosis result? Only in a few exceptional cases. Generally there is liga-

mentous union with more than normal mobility, and yet with enough firmness to give a useful limb.

Should *disease of the acetabulum* be an objection to the operation? If so, each of the above cases would have been thrown out, as in all it was found necessary to remove portions from the acetabulum. But even large pieces of the pubes and ischium have been removed with success, as in the remarkable case of Mr. Erichsen.

Should the operation be done if there is extensive *visceral disease*? In such cases we cannot hope for complete recovery of the health, but we may relieve the patient from pain, and prolong life; and under such circumstances the operation may be advisable.

If *hectic fever* exists, should the operation be done? The hectic fever may be due entirely to the condition of the joint, and in such cases will disappear when the source of irritation is removed. If, however, the hectic is due to tubercle in the lungs or to other disease that cannot be removed, the excision would be useless unless to relieve from pain.

If an *abscess* exists which has never opened, should it be opened first and the operation be done some time afterwards, or should it be opened at the time of the operation? If there is no urgency from pain, then it would be better to open the abscess during the excision, and not before, as there is apt to be depression after opening of such a chronic abscess, which would be probably lessened by the removal of the cause of irritation at the same time. But if there is much pain, then the abscess should be opened, in order to give relief to the severity of the pain, without waiting until arrangements can be made for the operation. I was lately called in consultation with Dr. Newcomet to a distant part of the city, and found a lad of about fourteen suffering intensely from a large and deep abscess at the hip, due to hip-disease. It was necessary to relieve the patient at once, and I promptly opened the abscess. It would seem advisable to wait until the patient has recovered from the effects of opening the abscess before resort is had to excision. I therefore advised in this case to wait for at least ten days or two weeks, if everything went well.

What *age* is most favorable for the operation? There seems to be a great difference in favor of childhood, and statistics would indicate that the best period is that between the ages of five and ten years. My own cases were, respectively, five, five, eight, seven, eleven, eight, seven, years old. Of these, the one that died soon after the operation, from erysipelas, was seven years of age, and the one that died one year after the operation, exhausted from a pelvic abscess, was five years of age at the time of the operation.

As regards the manner of performing the operation, it seems to me best to make the incision behind the trochanter, to allow of easy drainage from the wound. It should be long enough to allow of full exposure of the portion of the femur to be removed. A simple linear incision, extending above and below the trochanter, and slightly curved at the position of the trochanter itself, answers every purpose. It should be carried down straight

to the bone through the periosteum. The periosteum should be separated from the bone, and preserved as much as possible. The closer the operator keeps to the bone, the better: he injures the surrounding tissues less, and there is far less hemorrhage. The periosteum that is retained will aid in the recovery of the bone, and may, in part, reform the portion removed. It is easier and better to raise the head of the femur and carry the saw below it, than to make the section first by keyhole- or chain-saw beneath the bone without having disarticulated or raised it. The ligamentum teres being destroyed by the disease, there is no difficulty in raising the femur from the acetabulum, or from any other position it may have assumed. Care must be taken in moving the thigh, and but little force employed, as the femur can easily be broken, and this has been done in a number of recorded cases. If this should occur, however, good union may be looked for. The section with the saw had better be made below the trochanters, as otherwise the great trochanter is apt to press upon the wound and even to protrude. If any portions of the acetabulum or pelvis are found diseased, they should be removed by the gouge or forceps. A few sutures should be used to bring the edges of the wound together, and any simple dressing may be applied. I prefer that the limb should be placed in the extended position, and that it should be kept so by a moderate extending weight attached to the limb by adhesive strips. This plan is very comfortable to the patient, and enables the surgeon to dress the wound with greater facility than by any other method. The tendency of the muscles to spasmodic contraction is prevented, and the rough sawn extremity of bone is prevented from irritating the surrounding structures.

It has often surprised me to see the freedom from pain or serious symptoms after this capital operation; and, upon a review of the whole subject, I do not hesitate to recommend it to the careful consideration of every member of this Society, as I believe that the operation has not been done as often in this city as it would have been if the benefits accruing from it had been more generally understood.

QUININE IN PERTUSSIS.

BY JOHN W. KEATING, M.D.

BELIEVING that those more fortunate members of the profession who are placed by circumstances in a position to note the action of remedies in the treatment of epidemic forms of disease should make public the results of their investigations, I beg leave to add my few drops to the great river of experience.

In the early summer months of this year, while resident physician in the children's ward of the Philadelphia Hospital, I had occasion to see an epidemic of measles and whooping-cough, which diseases occurred at the same time and ran their course together. Owing to this fact, and also that, as all know, the children are none of the strongest, the mortality was rather large,—forty per cent. I was much interested at this time in the controversy

as to the possibility, by medicinal means, of cutting short an attack of whooping-cough, and I availed myself of the uncomplicated cases to test the remedies proposed.

From the first, I found quinine to be the most reliable.

The number of cases was large, and, as is usual in a hospital, the number of nurses small, so that I was obliged to abandon the idea of noting the frequency of the paroxysms in every case, and could only limit myself to the few who had their mothers constantly with them, and where the intellectual capacity of the latter enabled them to interest themselves in my experiments.

As an example, I shall narrate one case which was particularly interesting, as the disease was extremely severe, and was uncomplicated. This child was fifteen months old, had been sleeping with its mother, who was an assistant-nurse, in the room with the other children, most of whom had both whooping-cough and measles, and took whooping-cough, the attack of measles being deferred till a later period.

For twenty-four hours the mother carefully noted, by pin-holes in a card, the number of paroxysms. I then ordered one-half grain of quinine every hour during the day, the same dose to be given every two hours during the night. At the end of twenty-four hours I again had the "coughing-spells" noted. They had diminished in frequency exactly *one-half*. This experiment was often repeated, with the same results, until the end of a week, at which time the paroxysms were very few, but had not diminished in severity.

As an example of the same result in an older child, I may mention the case of a girl about fifteen years of age, who came to Philadelphia suffering from a severe attack of pertussis. The child was particularly annoyed by the severe nocturnal coughing-spells, which nothing seemed to relieve. I placed her upon the quinine-treatment, and the result was really wonderful; I may say that after the first day she coughed but little, and in less than two weeks the disease had entirely disappeared.

In order to avoid repetition, the conclusions which I arrived at are given, as follows:

1. That in most cases quinine, given in solution, will diminish the frequency of the paroxysms of whooping-cough, provided it be given in sufficiently large doses.
2. That quinine can be given to children in proportionally much larger doses than to adults, but that in very young infants it is contra-indicated, as it always causes vomiting.
3. That carbonate of ammonium will in almost all cases relieve the severity of the paroxysms, and consequently should be given in conjunction with quinine when this indication for its use exists.
4. That the dose of quinine for a child of two years should be at least ten grains daily, in divided doses: it should be watched carefully, and increased if it produces no effect. For a child of twelve years begin with fifteen grains daily, and note the effect of each dose. The drug should be frequently discontinued for a day or so, as it seems to lose its effect.

I merely offer this as the result of observation in one epidemic, for I know that the value of this treatment is acknowledged by some and denied by others.

RATTLESNAKE-BITE.

BY WILLIAM J. WILSON, M.D.,
Assistant-Surgeon U.S.A.

MR. JOHN R. MAGRUDER (son of the late Dr. Hezekiah Magruder, Washington, D.C.), now residing about twenty miles from this post, engaged in mining and smelting copper, informed me about three months since that one of his Mexican laborers had been bitten in the calf of the leg by a rattlesnake. Another Mexican went out, looked about for a few minutes, found a plant, chewed up some of its leaves, and applied the bolus to the wound, when the swelling (which had become considerable) disappeared in a short time, and the man recovered.

I requested Mr. Magruder to procure for me a specimen of this same plant, which I forwarded to Assistant-Surgeon J. J. Woodward, U.S.A., Surgeon-General's Office, Washington, and he sent it on to Professor Asa Gray, of Cambridge, who identified it as the "*Acerates decumbens*," or the "*Anantherix decumbens* Nutt.," a plant belonging to the milk-weed family.

My *experience* of its virtues is *nil*, as I have not been fortunate enough to see a case of rattlesnake-bite for a long time; but Mr. Magruder is a gentleman whom I have known intimately for the past two and a half years, and his statement is in every way reliable. I present it through your columns to the profession for what it is worth, and because I know from repeated inquiries I have made that the Mexicans depend upon it as an unfailing remedy. I would be very glad to have it tried in such cases, and the results published in some medical journal, for the benefit of myself and other members of the profession.

FORT BAYARD, N.M., Nov. 20, 1874.

A NURSERY SPRING-BOARD.

BY DWIGHT D. WILLARD.

THE sketch is a working one of a valuable hygienic appendage to a nursery, which I have had in use for years. Any blacksmith can easily make, of one-inch round iron, two frames, as shown, and erect them eight to ten feet apart. Placed upon the wall rather than upon the floor, they avoid the vibration and injury to the ceiling below, and also much of the noise. The noise can be still further reduced by india-rubber bearings attached to the spring-board.

This board—a plain strip of clear-stuff seasoned hickory—may be, say ten by one-half to three-fourths of an inch, giving any desired degree of elasticity. The middle of mine will barely touch the floor with my weight. It lies loose upon its supports, but projects a few inches, being kept from creeping by iron pegs in the edges, some three inches

apart on each side of either upright. A wooden cap (c) resting upon the tops of these uprights wards off harm from the children. It takes up no room, as it perfectly answers for a seat or a low table; it will not break or wear out (quite an object with a play-

F. Floor. B. End-view of spring-board.

thing); it is always in order; it can be used by one or several at the same time; and it is the most popular article that ever went into a nursery. Accidents are almost impossible. The child should have something—say a wire window-screen—to grasp when it desires, and the exercise can vary from the lightest motion for a young baby, to the most violent jumping.

Mine is never tired of, and I largely attribute the overflowing vitality of my five youngsters to its constant exercise. It is not patented.

1714 SPRUCE STREET, PHILADA.

NOTES OF HOSPITAL PRACTICE.

UNIVERSITY OF PENNSYLVANIA.

SERVICE OF PROF. JOHN NEILL, M.D.

Reported by WILLIAM ASHBIDGE, M.D.

POPLITEAL ANEURISM—DIGITAL COMPRESSION.

J. S., white, unmarried, aged 42 years, male, was admitted into the hospital, October 28, 1874. He stated that he had always enjoyed good health, and had never been prevented by illness from working at his trade, which was that of a painter. Many years ago he contracted a syphilitic sore, which was followed by secondary manifestations. Upon admission he stated that six weeks previously, while aiding in raising a heavy ladder, he felt something give way in the popliteal space of the left leg, and upon examination, soon afterwards, found a pulsating tumor. In a short time the left foot and leg became congested, and he also had considerable pain in them, which, however, varied in intensity from time to time, and for relief from which he had taken large doses of laudanum. Three weeks after the accident, the physician who had charge of the case attempted to keep up digital compression of the femoral artery, but, as it was in the country, and skilful assistants could not be readily obtained, this treatment was only continued during twelve hours. Upon examination, it was found that the man had a popliteal aneurism upon the left side, which appears to be of about the size of a hen's egg, and of the sacculated variety. On the 31st of the month he was presented to the class, and, after discussing the relative merits of the various modes

of treatment of popliteal aneurism, the preference was given to that by digital compression, and it was determined to carry out this treatment with the assistance of some of the gentlemen of the class.

By auscultation over the heart and the origin of the great vessels, a bruit was detected which gave reason to fear that changes of an atheromatous character would probably be found in the arteries.

Digital compression was commenced at 10 P.M. on the 2d of November, and was kept up until 7 A.M. on the 5th; altogether for a period of fifty-seven hours. During the first night the patient bore the pressure pretty well, and dozed considerably when moderately under the influence of opium. The bladder was evacuated with the catheter at 12 M. on the 3d. During this day he took his food regularly, and the administration of morphia hypodermically was kept up. The foot was cold, and the collateral circulation did not seem to be well established. Pulsation was still to be distinctly felt in the aneurism, although it was not so marked as at first. During the night of the 4th and morning of the 5th signs of exhaustion became apparent, and but little opium was given. The bowels were opened freely and naturally on the morning of the 5th. When compression was discontinued at 7 A.M. on the 5th, the man was weak and restless, and suffered a good deal of pain, and for the relief of these symptoms the administration of opium was resumed. The foot was cold and livid in hue, and was surrounded with cotton, and bags of hot water were placed alongside of it. Tonics and stimulants were freely administered, and were borne; but, although food was taken in good amount, and apparently digested, the man's strength rapidly failed. On the 8th, no pulsation whatever could be detected in the tumor. On the 9th, blebs formed upon the foot, and the skin became darker and mottled. No distinct line of demarcation formed, but the redness slowly ascended the limb. On Saturday, the 14th, it was decided to amputate through the lower third of the thigh, without waiting for the formation of a distinct line of demarcation. The operation at this time was deemed advisable because the strength of the patient was rapidly failing, and, as the entire foot was gangrenous, it was feared that in the condition in which he then was he could not much longer sustain the exhausting process which was going on. The amputation was performed before the class on the 14th; oval skin-flaps followed by a circular section of the muscles being made. The cut edges of the femoral artery manifested a decided tendency to erosion, and many of the muscular branches were enlarged so that numerous ligatures were needed; venous blood issued in jets from the vein, and that vessel was also tied. But a small amount of blood was lost during the operation, and the stump was soon closed and dressed. The man reacted but slowly, and moderate doses of brandy were given him. Until Tuesday, the 17th, his condition was tolerably good, but on that day his appetite failed. On the 18th, the dressings which were applied to the stump at the time of the operation were removed. The anterior flap was found to be pale and bloodless, presenting an appearance which was not at all satisfactory, while the posterior flap looked very well. At 1 A.M. on the 19th violent hemorrhage occurred, and so much blood was lost before it was entirely controlled that death occurred at 2 P.M. on the same day. No post-mortem examination was obtained.

The aneurismal tumor, upon examination, was found to be of the size of an egg, and sacculated, and was entirely filled by a firm laminated clot. An effort was made to inject an antiseptic solution into the vessels of the portion of the leg which had been amputated, but it was found to be impossible, as they were evidently in a very abnormal condition.

TRANSLATIONS.

SPONTANEOUS COMBUSTION. — M. Chassaniol, of Brest, recently presented to the Société de Chirurgie a communication on this subject. From the report of M. Horteloup on this paper we extract the following:

After having shown that no person worthy of credence had ever been present during a spontaneous combustion, and that in consequence science possesses no authentic facts on the subject, he passes in review the various experiments and different theories which have been proposed for the explanation of this phenomenon.

The most ancient notion was that the long-continued use of alcohol might, by impregnating the tissues with this fluid to the point of saturation, provoke spontaneous combustion. But it has been demonstrated that dead bodies or portions of the same, immersed for a longer or shorter period of time in spirits of wine, burn with great difficulty. It has also been attempted without success to set fire to the expired air in animals into whose veins ether and alcohol have been injected.

Spontaneous combustion has also been explained as the result of the action of electricity. It has in addition been attributed to the presence in the human body of a gas inflaming spontaneously on the approach of a light; but precise analyses demonstrate the absence of the phosphurets of hydrogen in all parts of the economy. Of late years it has been sought to refer the occurrence of spontaneous combustion to the same causes as in the case of spontaneous inflammation of various porous bodies, such as straw, hay, flax, etc. Here, again, the comparison is impossible, since combustion is due in these cases to the influence of chemical phenomena, the conditions of which are not found in the human organism.

It is thus seen that it is impossible to form any theory which shall admit spontaneous combustion. M. Horteloup does not conclude that the idea is to be entirely rejected; he simply maintains with Tardieu that it is not theory and experiment to which appeal should be made, but rather observation.—*Bull. Gén. de Thérap.*, Nov. 15, 1874. A. V. H.

THE ANTIPYRETIC TREATMENT OF FEVER (*New York Medical Journal*, November, 1874).—Dr. Leroy M. Yale, in an able and elaborate paper, endeavors to make evident the following propositions:

1. That there is an exact regulation of the heat of the human body in health, the production corresponding to the loss, but that excessive abstraction of heat may overcome the power of production.
2. That the same laws govern the high temperature of fever, with the exception that the producing power is more speedily exhausted.
3. That the danger in acute pyrexia is due not so much to consumption of tissue and consequent exhaustion, as to tissue-changes incompatible with life, caused by the elevation of temperature, and that this danger is proportional to the height and continuity of the fever.
4. That the indication is to abstract heat and limit its production in all cases in which the temperature is so high as to make the danger from it greater than that from exhaustion.
5. That in the use of cold water we possess an agent adequate to overcome the heat-producing power.
6. That we possess certain drugs that have the power of interrupting the excessive heat-production.
7. That the statistics of the antipyretic method are exceedingly favorable, when compared with those of any other plan of treatment, for all forms of acute pyrexia, whether with reference to diminished death-rate or to mitigated suffering.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, DECEMBER 19, 1874.

EDITORIAL.

DR. ERICHSEN'S ADDRESS ON AMERICAN SURGERY.

WE have read with great pleasure the report of Dr. Erich Erichsen's address on the above subject, delivered at the University Hospital College, London. We cannot afford the space to reprint the report in full, but republish portions of it under the heading of "Notes and Queries." No doubt the address itself will interest more than would any of our comments, and, not having space for both, we postpone the latter.

LEADING ARTICLES.

"BERMUDA AS A WINTER RESORT FOR INVALIDS."

ON the approach of a season like the present it becomes the duty of many physicians to give advice to their patients (particularly those having phthisis) as to a sojourn in a more mild and equable climate.

It is not my purpose to speak of the various places which are recommended for consumptives, but to refer only to one, and that the Bermudas.

Of them I speak only because quite recently a circular or pamphlet containing an account of the Bermudas (a reprint from *Harper's Magazine* of March, 1874) was distributed to a number of physicians of this city by the agents of the "Quebec and Gulf Ports Steamship Co."

The account is charming, and one which would elevate the waning hopes of an invalid, as well as invite the tourist.

The trite old adage of "One story is good till another is told," is applicable here. A letter bearing date Bermuda, March 12, 1874, came under my observation, in which the writer alludes to the *Harper's* article, and says, "You may contradict the part on climate from my own experience," and farther on says, "Pray do, in the cause of humanity, keep consumptives at home." Having friends who have *spent two winters* in the Bermudas, I sought information, and this is the purport of the reply: "Never send a consumptive to the damp and variable climate of Bermuda." The voyage is rough, and attended with danger. There is lack of suitable food for invalids, and much of what is to be obtained is sent from here. "The climate has become colder, with fearful storms," and, though the sun be warm, the stone houses are cold and damp, with mould upon the walls, and but little convenience for fires, this being the case even in the best hotels. Extortion is practised whenever a safe opportunity presents. My informant further states, "If you had seen the sick suffer for the ordinary comforts of life, as I have, you would urge them to stay at home."

As confirming the above statements, I here give a letter which appeared in the *New York Post* in May last.

"TO THE EDITORS OF THE EVENING POST:

"The article on Bermuda in your paper of Tuesday, May 12, is so erroneous in important particulars that the writer is prompted to urge the publication of a refutation.

"Permit the travelling public to learn truth from dear experience, but do not permit consumptives, who are infinitely better off by their own firesides than in Bermuda, to be deceived. In the city of Hamilton there is one private boarding-house, accommodating five persons; of hotels, the Metropolitan, second class, where no Americans stop, and one similar to it on Front Street, kept by a colored woman.

"The choice of the invalid public is therefore the Hamilton Hotel, which is finely situated, but so wretchedly kept as to be almost beyond description. In this house the writer spent three months of the past winter. The diet was monotonously bad; the walls were mouldy from excessive dampness; and the thermometer as low at times as 45°. But four rooms in the house are adapted for fire.

"There were not two lines of steamers during the winter, and for nearly a month no tidings were received from New York. The steamer *Perit* broke her machinery on the December trip, after which she was laid up, and now she has broken it again. The *Canina* is seaworthy. The voyages of the former have seldom been less than a week in duration, while the latter, belonging to the English line, is fast.

"But the passage is stormy and dangerous at best, lying in one of the most turbulent latitudes of the ocean. Well have the 'still vexed Bermoothes' maintained their reputation since Shakspeare's day. The climate is too variable for pulmonary disease, and a weather-record kept by an invalid this year showed the following result:

in the month of January, twenty-one days of rain; in February, fourteen days; and in March, twelve days, with gales of fearful weather, and a hail-storm about the roth which penetrated the roofs of the soldiers' huts at Prospect.

"Bermuda has been written up extensively of late by those interested in its advance, but, in the cause of humanity, do not allow the dying to go there ignorantly to shiver and starve.

"The statements with regard to the army and navy are entirely over-estimated. There are two regiments of one thousand men each, and a small corps of engineers, while of men-of-war not more than six have visited those waters in many months.

"Bermuda's prosperity passed away long ago, but was galvanized into transient life by the blockade, when she made money at our expense. The climate alone will prevent her becoming a resort for invalids, however much the proprietors of the steamships may desire it.
E."

With such pictures as these (and a personal knowledge of the writers of these letters enables me to vouch for their truth), we certainly cannot recommend to our patients such a place for the winter. One of the writers suggests Nassau, Cuba, and Santa Cruz as fitter places.

A. C. W. BEECHER, M.D.

CORRESPONDENCE.

MILK-SICKNESS.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—We are having this fall a regular epidemic of what is generally called milk-sickness or trembles. I have treated upwards of thirty cases.

In the subacute form, the individual is languid, and unable to make any exertion of body or mind; the appetite is variable, the bowels rather torpid, palpitation of the heart and slight stiffness of limbs are complained of, general tremblings are present, and if any considerable exertion be made, or if the taking of food be left beyond the usual time, nausea is felt.

In the acute form, the individual is suddenly seized with extreme nausea, prolonged vomiting, faintness, and prostration. The temperature of the body and extremities falls below the natural standard, but not more than one to two degrees.

The skin grows cold and clammy; great distress and anxiety are depicted on the countenance; the breath acquires a peculiar odor, as does also the whole body; the tongue is generally natural, moist, and clean, although the bowels become obstinately constipated. A complete loss of function in the stomach comes on, with incessant emesis. At every effort of vomiting, a fluid is ejected, of variable appearance: it is sometimes colorless, at other times like indigo-green, and sometimes like coffee-grounds.

As the disease advances, sharp pains in the limbs and neck are experienced, as well as acute gastric pains,

accompanied by a peculiar and intense sense of heat in the mouth. The patient is continually calling loudly for water or ice. The pulse is more frequent than at first. At the beginning of the disease it is generally about forty to fifty; after four or five days it rises to sixty or eighty, or even beyond this.

The nature and cause of the affection are not known. The poison is in the milk and butter, as I have treated cases where persons in the country had the disease, and the persons in the town who used the butter made in the affected dairies were also attacked.

The treatment here generally employed is simple: calomel, and ice in the mouth, with whisky freely administered as the main portion of the treatment. Blistering is not used as it formerly was, which is also true of opium. Of my thirty cases, all are now well; one patient had the disease five times,—once a month.

C. H. SMITH.

KENTON, OHIO, Nov. 20, 1874.

POISONING BY ODONTOCROLL.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—Allow me to offer to your notice a case of peculiar interest in my practice. My only apology for so doing is to inquire if there are parallel cases on record, and, if so, the principal points of their treatment. It is interesting to the profession, for the reason that the compound afterwards mentioned is in use among our dental brethren, and any practitioner may be called suddenly to a similar case, and be at a loss how to act,*as I was.

I was hastily summoned, on Monday evening, the 19th ult., to administer electricity to a man, supposed by the messenger to be dying, who had been carried to a physician's house. The patient, Mr. W., is a chemist, and, during the practice of his profession, has discovered a combination of hydro-carbons which had been found by himself and a dentist of eminence to be a very successful remedy for odontalgia. The compound, called "odontocroll," or "carvocroll," is a heavy, oily liquid, of smoky odor and taste, and has been introduced in the dental market as a local anæsthetic for toothache. Mr. W., the dentist, and a friend met in the chemist's laboratory, in this city, and further tested the drug by placing a few drops upon smoking-tobacco and inhaling the vapor. Mr. W. placed ten drops in his pipe, and, having smoked in the usual manner for a few minutes, poured ten more drops in it. After puffing a few times, he suddenly dropped, insensible, upon the floor, but in a few seconds revived entirely, and insisted upon resuming his smoke. To this his friends objected, and, during the discussion following the refusal, he again became insensible. They then removed him about two blocks, to Dr. D.'s office, and on the way thither he fell to the sidewalk, "collapsed," two or three times. This happened at nine P.M. I reached him at ten, and while I was listening to his story he fell upon the floor again, unconscious.

This had happened several times since he had reached the office. Upon examining him during his fall, I found the countenance somewhat dusky, the pulse normal in force and frequency, all the voluntary muscles relaxed except the abdominal, and the pupils responding quickly to light. I endeavored to arouse the breathing, which was completely suspended, by placing one pole of the battery over the right phrenic nerve, and the other over the stomach, using the current from one cell, interrupted and secondary. This I repeated during two successive attacks; but the electricity did not seem to quicken the return to consciousness or respiration. The only appreciable effect was to make him complain of great weakness as soon as he could speak, and, fearing the too prolonged influence of the battery, I suspended its use. The suggestion was made that another physician should be summoned, and an old experienced practitioner was called in at eleven. He advised the administration of brandy, of which about half an ounce was given. The attacks gradually became less frequent, and, after some time, gave premonitions of their approach by grimaces and bodily contortions, which were invariably followed by the insensibility. At half-past twelve we called to our aid two policemen, and removed him to his home, about three blocks distant. He struggled hard all the way, evidently from the effect of the brandy, but as soon as he was placed in bed became quiet, and had no more attacks during the night. In the morning he reported himself as feeling as well as usual, though somewhat weak and sore from his falls and struggles on the way home.

The unconscious state lasted usually from twenty to thirty seconds, came on suddenly, and passed off as quickly as it came on. During this time respiration was entirely suspended, and all sensibility lost. The conjunctiva and dorsum of the tongue were repeatedly touched without producing any reflex muscular action, and his appearance was that of a person in a state of complete anæsthesia. While conscious, he acted as usual in perfect health, nor was he himself aware, by any premonitions, of an impending seizure. Nothing was given him but some aromatic spirits of ammonia and the brandy mentioned.

Will you be kind enough to offer me such suggestions as to the cause or treatment of the case as your valuable time or space will permit?*

P.

BRIDGEPORT, CONN., November 19, 1874.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

CONVERSATIONAL meeting, November 18, 1874. President, Dr. WASHINGTON L. ATLEE, in the chair.

Dr. H. LENOX HODGE read a paper on *Excision of the Hip-Joint in Chronic Arthritis or Hip-Disease, with analysis of seven cases of the operation.*

* The editor of the *Times* knows nothing about the action of odontocroll, and whilst exceedingly interested in the account of the poisoning, whose symptoms were very strange, is unable to throw any light upon the matter. Can any of our subscribers do better?

Dr. J. C. MORRIS asked whether he had observed an excess of phosphates in the urine.

Dr. HODGE said he had not. His attention was particularly called to the urates, as the digestion is not good. The urine is generally clear.

Dr. L. K. BALDWIN asked whether any trace of syphilis was observed in connection with the cases.

Dr. HODGE said he had no proof of syphilis in connection with any of the cases.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

VICE-PRESIDENT, DR. H. LENOX HODGE, in the chair.

THURSDAY EVENING, OCT. 22, 1874.

TUBERCULOSIS of the kidney—Peculiar "worm-like" bodies from the urine of the same case.

Dr. R. M. BERTOLET presented the specimens for Dr. THOMAS B. REED, who gave the following history:

"The pathological specimens just shown are from a patient of mine, A. B., aged 35, of American parentage, who came under my professional care some ten days ago, with an acute attack of nephritis. Always of comparatively robust health (father still living at sixty, mother died of some acute fever, one sister of acute tuberculosis of the lungs at an early age), having served throughout the war, he came first under my notice professionally in 1869, and was treated for several months for 'stricture of urethra' (the result of gonorrhœa contracted in 1864, in the army) by gradual dilatation, from the finest 'catgut' to a No. 19 bougie. Every four to six months since (1869 to 1874), I have passed a bougie, and I repeated the operation some six weeks before his death. He was a man in mercantile life, whose business required him to travel a great deal; of correct and temperate habits, and, so far as I know, never sick until his last illness.

"When called to see him, October 9, he was suffering from fever of a malarial type, from a severe cold which he had neglected, and from wandering neuralgic pains over the chest and abdomen, and severe local pain over the kidneys. He was promptly treated by a mercurial cathartic, active local counter-irritation, dry cups, etc., over the lumbar region, full doses of quinine, and moderate diuretics, and for thirty hours he seemed decidedly improved. The urine was highly albuminous, sp. grav. 1130, but there was no apparent deposit until the 12th. On this day was observed an acute pleurisy developed posteriorly over both lower lobes of the lungs, more decided on the left side, and large effusion into the chest, which was greater on the right, with consequent oppressed breathing, and the tough, viscid expectoration specially characteristic of this complication. Simultaneously were noted a *peculiar blanching of the face* and a *failure of the circulation*, indicative of *hemorrhage, and most alarming*. This was late on the evening of the 12th. On examining his urinal on the morning of the 13th, very large quantities of cylindrical worm-like bodies, about one to two lines in diameter and from two and a half to three and a half inches in length, were discovered in the peculiar, smoky, dusky-red urine, which showed to the eye (as was soon confirmed by the microscope) positive and extensive hemorrhage from the urinary organs. He continued to pass these bodies in greater or less quantity during the remaining forty-eight hours of life. No treatment was of the slightest avail. He was freely stimulated with tonics and astringents, active diuretics and diluents, thorough counter-irritation, cups, etc. He died of exhaustion (loss of blood and compression of lungs) on the evening of the 15th. His mental condition was clear till within a few moments of

his death. Relief by the aspirator would have been tried had there been the slightest probability of averting the result.

"The post-mortem examination was made twenty-four hours after death, and was confined to the thoracic and abdominal organs. There were large effusions into the pleural cavities, with pleuritic exudations over lower lobes of both lungs, greater over the left. No evidence of tubercle in lungs. Liver apparently healthy; dark blood escaped from portal veins upon section. Mesenteric glands not enlarged. The bladder was contracted and empty; its mucous membrane and that of the right and lower half of left ureter presented no pathological lesions.

"*Left kidney* moderately enlarged, of doughy consistence; its cortex smooth, yellowish-white in color, with clearly developed *stellule Verheyinii* and injection of the Malpighian bodies,—the latter seen as red dots; nearly all of the medullary papillæ intensely congested, purplish in hue. Pelvis and ureter healthy. The thin capsule easily separated, and was covered with a stout layer of adipose tissue.

"*Right kidney* somewhat larger and more congested, with the same alterations of the parenchymatous structure as noted in the opposite organ. But in addition there are seen disseminated at numerous points both in the cortical and medullary substances, also in the capsule itself, small round tubercular nodules of variable size and color. None of these tubercles have attained a size greater than that of a small shot, the larger ones having an opaque, yellowish aspect, while the smaller are gray and transparent.

"The mucous lining of the pelvis is thickly strewn with granules, many of which have softened into continuous cheesy patches, forming large, irregularly-shaped ulcerations. The underlying connective tissue is greatly hypertrophied. There is extensive loss of substance of several of the central papillæ, the tubercular infiltration and ulceration extending upwards into the cortex.

"The upper half of the left ureter is apparently filled with a clot half an inch thick. The mucous membrane of this portion of the tube is studded with minute gray tubercles. A more careful examination clearly shows that the clot has been formed not within the lumen of the tube, but by extravasations between the mucous membrane and the outer coats of the ureter.

"Microscopically, both kidneys presented fatty degeneration of the renal epithelium, with slight hyperplasia of the interstitial connective tissue. The presence of giant multinuclear cells and lymphadenoid structure in the gray granules of the left kidney confirms the diagnosis of true miliary tubercle.

"The softened cheesy foci (probably embolic) situated in the cortex, although only of the size of a bullet, evidently proved the source for the local infection, since the bladder and genito-urinary organs were not, as is usually the case in renal phthisis, involved in this instance.

Remarks.—"The right kidney clearly showed erosion of some of the vessels of the kidney, with subsequent hemorrhage and rupture of wall and the pouring out and infiltration of the fatty and cellular tissue surrounding the pelvis of the kidney and ureter, forming a large, irregular mass which at first sight suggested the idea of malignant disease of the organ. When the kidney was lifted from its bed, a large mass of coagulated blood was found lying in the retro-peritoneal region, amounting to several handfuls. Here, then, was the cause of the blanched face and failing circulation. From the eroded arteries and ruptured wall of the kidney his life-blood had slowly and silently ebbed away.

"Some of the questions involved in the treatment and subsequent post-mortem examination of this case are of interest.

"The hemorrhage and its cause are of special moment.

"(1) Malignant disease (cancer) or traumatic injuries are the chief sources of hemorrhage from the kidneys. During life, and, indeed, until the determination of the question by the microscope, I was of the opinion that malignant disease (cancer) had suddenly been developed in this case. Tubercle in other organs—the lungs, for example—is not, as a rule, attended with hemorrhage, but, as in gangrene, seals up the vessels as it advances; and in looking up the authorities on the subject I do not find any mention made of hemorrhage as an element in any discussion of the subject of tuberculosis of the kidney.

"(2) The presence of the cylindrical worm-like bodies, which were probably composed wholly of blood-corpuscles and fibrin, and the probable manner of their formation. There were three possible modes thought of. Aitken and Vogel state that 'they have been seen, and are possibly formed by the passage of blood through the urethra.' This, if it was passed slowly and through a stricture, might be a satisfactory explanation; but in this case no stricture existed, as a No. 19 bougie had been passed within a few weeks of death, and the passage of these bodies in great numbers at each act of micturition shows conclusively that they were formed before reaching the bladder.

"Niemeyer, another author who mentions the subject, says 'that they are sometimes formed in the ureters,' but fails to state under what circumstances.

"In the case before us this seems to me the most intelligent way to account for their formation. As stated in the post-mortem account, the hemorrhage which was poured out into the fatty and cellular tissue in and around the pelvis and the origin of the ureter *coagulated and formed a semi-solid mass encircling the ureter and very greatly contracting its calibre*, so that while surrounded by this mass *only a small-sized probe could be passed*. The blood poured out in the pelvis of the kidney made its way with difficulty and drop by drop through the stricture, and coagulated in the ureter below this point.

"The third theory to account for their formation is in the straight or collecting tubules of the kidney. The masses seem to me too large to be accounted for in this way; and yet the microscopic appearances of some of the specimens of Dr. Bertolet show what seem to be the branching tubules coming off from the straight tubules.

"To his very able assistance in the post-mortem and microscopical investigation of this case, as well as in the discussion of the various theories and authorities on the subject, very much of the interest of the case is due."

Examination of urine and worm-like bodies by Dr. Bertolet.—"The urine had a specific gravity of 1030, an acid reaction, highly albuminous, contained granular and blood casts, free blood-corpuscles, besides the numerous worm-like bodies seen floating in the reddish-brown-colored fluid. These worm-like bodies are more or less tortuous in outline and dark red in appearance. Their average length is two inches, width one line and under. Very many of them end in a thin filamentous appendage, so tenuous as to be scarcely visible to the naked eye. A few of these terminal extremities, when examined microscopically, present a dichotomous appearance. These lateral branches are not due to any accidental folding, but seem to be in actual continuity with the main trunk.

"Microscopically, these casts are made up of coagulated fibrin and blood-corpuscles. Renal epithelium is seen adherent at points along the minuter filaments only. The question at once arises, At what point were these remarkable casts formed? While the wider portions of them were unquestionably moulded in the constricted part of the ureter, the terminal parts are most probably casts of dilated straight tubules.

"The adherent renal epithelium, the branched appear-

ance, and the fact that sections of the medullary cones still reveal the presence of blood-casts in some of the tubules, while others are seen empty and deprived of their epithelium, lead me to regard the tail-like end attached to some of these worm-like bodies as being formed in the uriniferous tubules. That they should have been washed from thence and become adherent to the masses, plugging the ureter, seems to me no more improbable than that the clots should have been expelled from the latter site. Beale and other authorities state the diameters of the largest tube-casts to be from one five-hundredth to one two-hundred-and-fiftieth of an inch. Yet, upon considering the unusual and enormous pressure to which the uriniferous tubules of this kidney must have been undoubtedly subjected by the blood damming up into them, I believe that the finer portions at least of these worm-like bodies were formed in the straight tubules, and not in the ureter."

Dr. H. LENOX HODGE inquired how soon the patient died after the passage of the worm-like bodies.

Dr. REED replied that they were passed on Tuesday morning, and the patient died on Thursday.

Dr. HODGE inquired whether there was hemorrhage into any other organ.

Dr. REED thought the death of the man was owing to a large hemorrhage about the kidney, behind the peritoneum, in connection with the acute pleurisy with which he was suffering. There was no hemorrhage in any other organ.

Dr. J. G. RICHARDSON observed that to his eye the so-called "branch" of the cast shown by Dr. Bertolet presented the appearance of being a narrow strip of the main stem, split or torn off the side for a short distance, instead of showing the characters of a smaller cast from the lumen of some tributary tubule emptying into the larger stricture.

He further remarked that he had never seen a tube-cast larger in diameter than the one three-hundredth of an inch, and that the largest recorded by Beale was the one two-hundred-and-fiftieth of an inch; whereas the bodies presented by Dr. Bertolet were, when fresh, as thick as the one-sixth of an inch. He also thought that so large a dilatation of the uriniferous tubules as would be necessary for the formation of these bodies would be visible after death. Dr. R. suggested that the bodies might be formed in the ureter, whose walls are often in contact, and that the tapering form of the body might be owing to the fact that the farther from the immediate seat of hemorrhage the less would be the force of the blood and the smaller its quantity, so that a clot would gradually become narrower in its diameter as its extremity was reached.

Dr. MORRIS LONGSTRETH inquired whether blood was observed in the uriniferous tubules under the microscope.

Dr. BERTOLET replied that numerous sections had been made, and in some of the tubules blood-cylinders were still found.

Dr. RICHARDSON thought that blood extravasated into the pelvis of the kidney might force its way into the tubules.

The specimens were referred to the Committee on Morbid Growths, for further examination and report.

Two cases of intestinal perforation, the sequelæ of typhoid fever.

Dr. F. P. HENRY presented the specimens,—perforation of the ileum consequent upon ulceration of Peyer's patches. Both of the subjects furnishing these specimens were walking cases of typhoid fever. The first case, from which the specimen in alcohol was obtained, was admitted to the Episcopal Hospital on the 9th of May, and died on the 5th of June. For the first four days after admission he remained in bed, but during the greater part of his stay of nearly a month in the

hospital he was up the most of each day. He was easily fatigued, however, and subject to headache and dizziness. This latter symptom, dizziness, was his chief complaint, and, taken in connection with his slow pulse, anorexia, and frequent headache, was calculated to draw attention to the brain as the seat of disease. This dizziness was so great as to cause him to adopt a peculiar gait to steady himself. Dr. H. noticed him one day walking with his legs very wide apart, and on questioning him found that it was to prevent himself from falling. His temperature was found so near normal that no record of it was preserved until June 1, when the doctor observed it recorded as 101° ; this being the evening temperature.

On June 2, the morning temperature was 99° , and the evening, $100\frac{1}{2}^{\circ}$.

On June 3, morning, $98\frac{3}{4}^{\circ}$; evening, 100° .

June 4.—Morning, $99\frac{1}{2}^{\circ}$; evening, $104\frac{1}{2}^{\circ}$. It was at this time that symptoms of peritonitis showed themselves. There was enormous tympanitic distention and great tenderness of the abdomen, with a pulse of 140. The pulse was taken again during the night, and found to be $105\frac{1}{2}^{\circ}$.

The man died before morning, in a state of collapse, the result of shock. At the post-mortem, a few hours after death, there was found a small quantity of watery fæces in the abdomen, and a few patches of opacity, with increased vascularity, upon the peritoneum covering the small intestines. The ileum was thickly covered with ulcerated Peyer's patches, and after careful search a small perforation was discovered at the bottom of one of these ulcerations, a few inches above the ileo-cæcal valve.

This patient was kept upon liquid diet, as a strong suspicion of typhoid fever existed, and the ulceration cannot, therefore, be considered due to a traumatic cause.

The second case was admitted to the Episcopal Hospital on the 12th of October, 1874. He had been ill for five weeks previous, but had not been confined to bed. His symptoms were headache and fever, always worse towards evening; pain in the right iliac region, and diarrhœa, amounting to from fifteen to twenty stools in the twenty-four hours. Six days before admission to the hospital, he was suddenly seized with nausea and vomiting, the diarrhœa continuing, with pain accompanying each passage.

On admission, there was excessive tenderness over the whole abdomen, great rigidity of the abdominal muscles, particularly the recti, and vomiting at frequent intervals of a small quantity of pale-green fluid, apparently mucus, tinged with bile.

Dr. H. first saw the patient on the 13th, the morning after his admission, and found the above-mentioned symptoms. The decubitus was dorsal, with the thighs and legs flexed. The pupils were moderately contracted; respirations eighteen per minute and very shallow; pulse 160, weak and thready; skin cool and moist.

The treatment followed by Dr. Steele, the resident physician, had consisted of a grain of opium, in pill, every three hours, with a hypodermic injection of one-quarter of a grain of morphia every six hours, with nutritious enemata.

Dr. H. administered one-quarter of a grain of morphia hypodermically, and on leaving the hospital found the respirations sixteen per minute, and the pulse still 160.

At 1 P.M. there was no pulse at the wrist, the respirations were fourteen per minute, and the pupils decidedly contracted. Died at 9 P.M.

The opium administered did not produce sleep or stupor, but served to mitigate the severity of the pain.

At the autopsy, eleven hours after death, the intestines were found matted together in one mass by, and bathed in, about two quarts of very offensive pus. Mesenteric

glands enlarged but not softened. Several ulcerated Peyer's patches were observed, but the ulceration was by no means so extensive as in the preceding case. At the bottom of one of these patches were found two rather large perforations, and a third at the bottom of a second ulcer. In these ulcerations the whole of the glandular structure has sloughed away, leaving a clean-cut ulcer, showing a late stage of the disease. The intestines are covered with a thick layer of lymph.

The notes and observations in connection with these cases were by Drs. Steele and Reid.

Fluid removed from a cyst of the broad ligament.

Dr. H. LENOX HODGE presented the specimen, from a woman 52 years of age, who had suffered from the swelling for four years. On October 9, Dr. H. tapped her, and removed ten quarts of this colorless, transparent, thin fluid. It is slightly opalescent, and looks like pure spring-water. Its specific gravity is 1004, and it does not coagulate on boiling. Upon standing it has become less clear than at first, and a thin pedicle has formed upon its surface. Under the microscope, Dr. Richardson reports that the field is free from objects.

There is a property which Dr. H. thought this thin fluid possessed, and to this he wished to direct the attention of members of the Society, namely, *its power of transmitting sound*. Upon auscultating the abdomen of this patient, the gurgling of the intestines could be distinctly heard in front where the sound on percussion was dull. In other cystic dropsies of the abdomen he had not noticed this symptom. It may possibly prove of value in detecting the existence of cysts of the broad ligament and in distinguishing them from other collections of fluid. Their diagnosis prior to tapping is somewhat difficult, and anything that will aid in recognizing them is of value.

REVIEWS AND BOOK NOTICES.

INFANT DIET. By A. JACOBI, M.D. Revised, enlarged, and adapted to popular use, by MARY PUTNAM JACOBI, M.D. G. P. Putnam's Sons, N.Y.

The peculiar combination of authorship in this little work gives one an exceptional interest in its perusal. Surely, if ever woman falls as a practitioner into her appropriate place, it will be as a director of infant management and an adviser of the mothers of our race.

A proper diet for infants deprived of the breast would save, in our large cities, more lives than an infallible specific for pulmonary consumption. While the world is filled with so-called infant foods, from that of the great Liebig to that of the small apothecary who seeks fame and fortune at the infant's mouth, the recipients, with singular unanimity, condemn them all in unmistakable pantomime, too often ending in tragedy, the baby actor falling at last before the well-directed blows of even the most highly respectable articles. Yet how seductive the allurements! how voluminous the catalogue! how highly recommended each unfailling substitute for that fountain which seems destined never to admit a rival! Ingenuity has given us not only the names, but, with a gush of generosity, the articles known as farina, maizena, cerelina, papoma, nutrina, prepared wheat, barley, malt, oatmeal, corn starch, and so on to the end of the catalogue. Yet, in the very midst of this gushing plenty, the summer months sweep away their victims, and the rest of the year gleans the plenteous fields.

Though advocating the claims of no new aspiring food, this book aims rather at a sensible use of what means we have, and will prove suggestive to many practitioners, and one that can be recommended to

intelligent mothers. We do not intend in our brief notice to discuss the propriety or value of all its recommendations, but only say, Find us a work of the size and kind better, or as good.

With as little technicality as is consistent with an honest treatment of the subject, the language never descends to that mock simplicity which is the bane of so many works "adapted to popular use." We are sure that if popular medical works must be written, the true principle in their composition is that set forth by the authors of this one in their preface,—that science will not bear too much dilution, and that even non-professional readers, even the mothers who may read this book, have some brains, as a rule, and resent being addressed, as they so often are, in what may be called medical baby-talk. E. W. W.

CLINICAL LECTURES ON VARIOUS IMPORTANT DISEASES.

BEING A COLLECTION OF THE CLINICAL LECTURES DELIVERED IN THE WARDS OF MERCY HOSPITAL, CHICAGO. By NATHAN S. DAVIS, A.M., M.D., Professor of Principles and Practice of Medicine and Clinical Medicine in Chicago Medical College. Edited by FRANK H. DAVIS, M.D. Second Edition. Philadelphia, Henry C. Lea, 1874. Pp. 283.

This effort to instruct the profession from the numerous cases of disease treated in Mercy Hospital is certainly a meritorious one, and the records so carefully compiled by the younger Dr. Davis doubtless contain many observations which, if they had been published in the year of our Lord 1800, would have possessed great value.

During the current century, however, sundry wonderful discoveries in the branches of pathology, diagnosis, and therapeutics have been made, so that at the present day scientific physicians, even of "the younger class" (for which, the preface tells us, this book was especially designed), are apt, at least in this longitude, to demand that recent medical works should enable them to learn something not fully set forth in the pages of Sydenham and Cullen.

Our space is too limited to permit us to point out to the Doctors Davis, for their own benefit as well as that of their *students* and *patients*, many of the improvements in the healing art of which they appear to be practically ignorant. As an aid to diagnosis and prognosis, we would, however, recommend to their notice an ingenious instrument called the clinical thermometer, whose precise indications of temperature far exceed in value those expressed by the inexact phrases "skin cool" (p. 167), "skin dry but not hot" (p. 29), "skin dry and warmer than natural" (p. 27), etc., etc. Conscience forbids us to conceal any longer from Prof. Davis that a modified form of the antique magnifying-glass (with which he is doubtless familiar) might, by revealing those remarkable microscopic cylinders denominated tube-casts, add much to the certainty of his diagnosis of Bright's disease, for which he now ("1874") seems to depend solely on the history, the general symptoms, and the presence of albumen in the scanty urine (p. 171). We further feel it a duty to inform our authors that a certain Prof. Niemeyer has pointed out some broad distinctions between tuberculosis and phthisis, which throw important light upon the diagnosis and treatment of these affections. And lastly, we beg leave, out of pity to the poor sufferers from neuralgia now lying in Mercy (?) Hospital, to suggest that the "temporary relief" should sometimes be afforded them *at once*, by that precious boon to humanity, the hypodermic syringe, instead of forcing them to wait hours for a partial mitigation of their agony by the ancient, tardy, and inefficient methods of using "anodyne liniments" (p. 190), or calomel and opium (p. 205). R.

GLEANINGS FROM OUR EXCHANGES.

PYÆMIA (*The Lancet*, November 14, 1874).—Dr. W. Moxon believes that, after a survey of the indications of its morbid anatomy, he must regard pyæmia as made up of blood-disease and local inflammations. We can trace several ways in which the blood-disease and local inflammations are related to each other.

First. The general disease may greatly predominate, so that the blood becomes unviable, and death occurs with signs of blood-poisoning, revealed during life in the form of high fever and rapid fatal exhaustion, and after death by softening of the great viscera and extravasations of blood and ecchymoses within the tissues, no local suppurations being found.

Also, here we must remember that some cases of pyæmia of a most characteristic kind are found without any kind of sore whatever; we should not say this so strongly unless we had, in several instances, searched with the utmost care through all parts of the body and found no primary disease.

Secondly. In another kind of pyæmia the wound or sore produces a morbid matter, which is absorbed, and so poisons the blood. It is probable that the pyrexia of surgical fever is principally caused by the absorption of the products of the wound; so that this kind of pyæmia is allied to common surgical fever. The prevention of putrefactive changes in the discharges of the wounds averts the danger of pyæmia from this cause; and the success of the antiseptic method shows sufficiently the importance of this source of blood-poisoning. It creates, however, only one kind of pyæmia, characterized by its appearing later, and running a more chronic course, with secondary suppurations.

It is believed by some that there is a pyæmic *contagium*, which acts first upon the wound, and enters the system there; but further observations are required to substantiate this hypothesis.

Thirdly. In some cases that go by the general name pyæmia, the whole affection is confined to the formation of purulent thrombi in the veins, and the conveyance of these to the lungs as emboli, where they set up secondary suppurations. Such a process is too simple and clear to need further remark.

These views may be thus summed up: Simple embolism, or purulent absorption, or general fever due to contagion, severally form distinct varieties of what is called pyæmia; but in many cases, perhaps the majority, all these conditions exist together.

PHOSPHORUS AS A STIMULANT (*The Lancet*, October 31, 1874).—Dr. John Brunton records the two following cases of the use of phosphorus as a stimulant:

A woman, aged 47, was in the twelfth day of typhus fever. Her depression was very great. She lay in bed cold, nearly pulseless, semi-unconscious, and with difficulty aroused, quite unable to move in bed; in short, she appeared moribund. One-twelfth of a grain of phosphorus was administered every two hours, with marvellous effect. The revivifying power was very marked, by return of heat, pulse, consciousness, and general power. Next day she had the turn, and has recovered admirably.

A man, aged 40, suffered from diarrhæa, which was very prevalent. In a day or two he had the appearance of having something more than mere diarrhæa. He became too ill to get out, and took to his bed. On examination, the characteristic rose-colored spots of typhoid fever were found, and he had all the other symptoms present. His fever continued gradually to increase; his conjunctivæ were injected, his breath cold, his skin cold and clammy; pulse 48, very weak and compressible; voice whispering; temperature 96.4°. He was

in a condition of extreme depression. Phosphorus was at once administered in doses of one-twelfth of a grain every two hours, and eighteen hours after, when he had taken three-quarters of a grain of the drug, he had quite revived. His skin was comfortably warm, eyes not so suffused, voice more natural; pulse 72; temperature 99°. The phosphorus was immediately stopped, and nitric acid was given. Since that he has gone on prosperously, and is now convalescent.

The formulæ used was—

R Ether. tinct. phos. (gr. $\frac{1}{2}$ to $\frac{3}{4}$), \mathfrak{z} iii;

Spt. vin. rect., \mathfrak{z} ss;

Glycerin. anhydry., ad \mathfrak{z} iss.

One teaspoonful as a dose.

SYMPHYSEOTOMY (*The Boston Medical and Surgical Journal*, November 26, 1874).—Dr. Piccinini, after a review of the operation of symphyseotomy, lays down the following rules:

1. Never perform symphyseotomy when the pelvis is contracted to less than three or three and one-half inches (80 to 95 millimetres).

2. Operate by the subcutaneous method.

3. After section of the cartilage, apply the forceps.

4. The position of the patient, on her back with a hard cushion beneath the pelvis, previous catheterization, and an immovable bandage are details of great importance to the success of the operation.

During five years there have been nineteen operations at the hospital at Naples, in fifteen of which the women were saved, and in sixteen the children.

NOTES AND QUERIES.

EXTRACTS FROM DR. ERICHSEN'S ADDRESS ON AMERICAN SURGERY.

"And first, as to the Profession, I may at once say that it appears to me to occupy in America, relatively to the rest of the community, a far higher social status than it does in this country. The reason for this seems tolerably obvious. In the absence of an exalted hierarchy in an established church and of great dignitaries of the law, these professions do not offer sufficient inducement for men of the highest intellectual calibre to enter them. Medicine therefore stands prominent as probably the best-educated, certainly the most scientific, and consequently, in a country where education is so widely diffused and so much regarded, the most respected, of the professions. And in the absence of all titled classes, it can socially more than hold its own in competition with the trading and financial elements which are such prominent constituents of the society of most of the American cities. Perhaps, also, the high position that medicine occupies is owing, in some respect, to the greater uniformity of practice that prevails among medical men in America than with us. For, just as in the Law there is no division into barristers and solicitors, so in Medicine there is none into physicians, surgeons, and general practitioners. Special aptitude, inclination, or opportunity will necessarily lead men to a greater eminence in particular departments of the profession. But the subdivision into classes and specialties, which is so prevalent here, is unknown in the United States.

"Surgery in the United States certainly stands at a very high level of excellence. The hospital surgeons throughout the country have struck me as being alike practical, progressive, and learned in a very high degree. In practical skill, and aptitude for mechanical appliances of all kinds, they are certainly excelled by no class of practitioners in any country. They are thoroughly up to modern surgery in its most progressive forms, and I have never met with any class of men who are so well read and so perfectly acquainted with all that is done in their profession outside their own country. It would be a great injustice to American surgeons for it to be supposed that surgical skill is confined to the large cities or to the few. On the contrary, I know no country in which, so far as it is possible to judge from contemporary medical literature, there is so widely diffused a high standard of operative skill as in the country districts and more remote provinces of the United States. The bent of the mind of the American surgeon is, like ours, practical rather than scientific; in fact, there are the same mental characteristics displayed in him that we find here,—the same

self-reliance, the same practical aptitude, the same *curative* instinct, which leads him to consider his patient rather as a human being to be rescued from the effects of disease or injury than as a scientific object to be studied for the advance of professional knowledge.

"One of the great advantages—and it is a very great one—that an English writer enjoys is that he addresses eighty millions of people, and that his works are not only disseminated throughout his own country, but, if of any value or importance, are eagerly sought after by that still larger body of readers existing in the 'Greater Britain' which now encircles the globe. And if it be true, as has been said, that the judgment of enlightened foreign contemporaries is an anticipation of that which posterity will give, he may possibly have a foreshadowing of the verdict that a future generation of his own countrymen will pass upon him, in the estimate in which he is now held among those who inhabit the regions beyond the Atlantic.

"Surgical practice in America does not differ in any very essential respects from that adopted here. There are necessarily some modifications, and many ingenious appliances; but essentially there is no greater difference between American and English surgery generally than is to be found between the practice adopted in any two London hospitals.

"The treatment of wounds is sufficiently simple, and presents nothing peculiar. I observe that American surgeons are careful about the drainage of wounds, and employ drainage tubes or similar appliances freely.

"Antiseptics do not appear to be much, if at all, employed; at least, in a methodical form. Carbolic acid in the form of lotion or wash is commonly used. Indeed, antiseptics are not so much needed in the American hospitals as in ours. The object of antiseptics is to prevent the contamination of a wound by septic impurities from without. These sources of contamination do not exist in such hospitals as those that I have been describing to the same extent that they do in less perfectly constructed and less hygienically conducted establishments, and hence antiseptics are proportionately less needed. In America it is attempted to accomplish by improved construction of hospitals, and by close attention to hygienic requirements, those great results which we are here driven to attain by 'antiseptic' methods of treatment. In consequence of the ignorance in all matters that relate to the hygiene of hospitals that prevails among the architects and managers of these institutions, an undue burden of anxiety, responsibility, and care is thrown upon the surgeon, who is now unceasingly engaged in combating septic disease; and in order to keep down that rate of mortality which is the direct consequence of septic hospital influences, he is driven to the employment of elaborate and complicated methods of antiseptic treatment. Cleanliness in its broadest sense is the best and most efficient antiseptic. If the constructors and conductors of hospitals were acquainted with or would adopt those hygienic rules on which hospitals should be built and managed, if hospitals were not overcrowded, if the system of ventilation was perfect, if there was a continuous water-supply, a proper isolation of wards and distribution of patients, the causes of septic diseases would not be generated. Those foul and filthy-begotten diseases, pyæmia and hospital gangrene, would disappear, and antiseptics, in the absence of septic influences, would become unnecessary. Contamination of hospital air would be prevented; we should not, as now under defective hygienic arrangements, first allow the pollution to take place, and then be driven to the use of antiseptics in order to prevent infection of wounds by the already septic-laden atmosphere. Under the present system we begin at the wrong end. Instead of preventing the possibility of atmospheric contamination by perfect hospital hygiene, we allow the septic poison to be engendered, and then, before it can be implanted on the wound, seek to destroy it by the employment of chemical agents.

"With regard to anæsthetics, I have little to say. Ether is invariably used at Boston, and is preferred to chloroform by many hospital-surgeons in other American cities. I saw it given in some operation cases at the Massachusetts General Hospital, which has the great honor and privilege of being the institution in which anesthesia was first employed in any surgical operation; it was administered here on a sponge, without any apparatus or complicated contrivance.

"Except in Boston, the Museums are still in an undeveloped condition. That of Dr. Mott, at New York, was unfortunately destroyed by fire; but Dr. Wood, with characteristic energy, is trying to establish one at Bellevue. At Philadelphia the splendid collection of Hyrtl's injections have lately been acquired by purchase. But there is one museum which is so unique, so admirably arranged, and so interesting that I must direct your attention to it for a few minutes. It is the Museum of the Army Medical Department at Washington. This magnificent collection, illustrating not only every possible variety of gunshot and arrow injury, but also those diseases which are more fatal than the bullet to an army in the field or in camp, has, under the able superintendence of Surgeon-General Barnes and of Drs. Otis and Woodward, been most admirably arranged

and catalogued. The collection itself is well known in Europe through the medium of those beautifully illustrated and ably collated medical histories of the great War of the Rebellion which have been published under the superintendence of the Medical Department of the United States Army. Many of the specimens in this museum are quite unique."

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—Having endured much fruitless discussion as to whether specialties are really a necessity of medical centres, and, if so, why so, I was greatly delighted to learn, from a communication in a late issue, that the necessity "occurs as the result of an organization in man which leads him to take cognizance of results as evidences are presented to him in the practical working of things."

We need, now, no more discussion of the subject: it may be considered definitely and finally settled by this lucid exposition.

Yours, gratefully,
D. S. M.

CAMP McDERMIT, NEVADA, November 25, 1874.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—Will you be good enough to inform me, through your valuable journal, of the extent of Mr. Durham's researches with regard to the condition of the brain in sleep, and when and where they were published?

I infer from the report of a meeting of the Royal Medical and Chirurgical Society, published in the *London Medical Times and Gazette* for October 24, 1874, p. 486, that Mr. Durham has advanced the theory that "narcotics" produce contraction of the blood-vessels. Eight months ago my preceptor, Prof. Eliot, of the District of Columbia, suggested to me the same theory as original, with a view to have it demonstrated, since which time the subject has engaged my attention and study.

Respectfully,
GEORGE M. KOBER,
A. A. Surg., U.S.A.

MARRIED.

November 12, at Maple Hill, Montgomery County, by Friends' ceremony, Miss FRANCES STOCKTON CORSON, daughter of Dr. Hiram Corson, to RICHARD H. DAY, of Philadelphia.

At Fort Bridger, Wyoming Territory, Miss ADA CARTER, daughter of Judge William A. Carter, to JOSEPH K. CORSON, Assistant-Surgeon, U.S.A., son of Dr. Hiram Corson, of Montgomery County, Pennsylvania.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

THE next conversational meeting of the Philadelphia County Medical Society will be held Wednesday, December 23, at 8 o'clock P.M.

Dr. J. M. Boissot will read a paper entitled "A Case of Purpura Hæmorrhagica requiring Transfusion."

All regular practitioners in the city are invited.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM DECEMBER 8 TO DECEMBER 14, 1874, INCLUSIVE.

SMITH, J. R., SURGEON.—Granted leave of absence for fifteen days. S. O. 242, Military Division of the Atlantic, December 9, 1874.

KINSMAN, J. H., ASSISTANT-SURGEON.—Granted leave of absence for nineteen days. S. O. 270, Department of Dakota, December 8, 1874.

MATTHEWS, W., ASSISTANT-SURGEON.—Assigned to duty at Fort Wood, New York Harbor, as Post-Surgeon. S. O. 241, Military Division of the Atlantic, Dec. 7, 1874.

BROWN, P. R., ASSISTANT-SURGEON.—Assigned to duty at Fort Hamilton, New York Harbor. S. O. 241, c. s., Military Division of the Atlantic.

FINLEY, J. A., ASSISTANT-SURGEON.—Assigned to duty at Fort Monroe, Va. S. O. 241, c. s., Military Division of the Atlantic.

BEDAL, S. S., ASSISTANT-SURGEON.—Assigned to duty at Fort Wadsworth, New York Harbor. S. O. 241, c. s., Military Division of the Atlantic.

WILCOX, T. E., ASSISTANT-SURGEON.—Assigned to duty at Fort Leavenworth, Kansas. S. O. 201, Department of the Missouri, December 4, 1874.

SATURDAY, DECEMBER 26, 1874.

ORIGINAL LECTURES.

CLINICAL LECTURE ON SCABIES.

Abstract of a Lecture delivered at the Hospital of the University of Pennsylvania

BY LOUIS A. DUHRING, M.D.

Reported by ARTHUR VAN HARLINGEN, M.D.

GENTLEMEN,—Before examining this patient we will obtain from him a few facts relative to the beginning of the complaint from which he suffers, and also some account of its course. He is an Englishman, healthy, and has never had any disease of the skin previous to that for which he now seeks relief.

When he landed in New York, six months ago, he was, to the best of his knowledge, perfectly well. He spent two nights in a boarding-house in that city, and then came to Philadelphia. Three weeks after his arrival here he first noticed an eruption on the left fore-arm, characterized by itching. This spread gradually from one point to another until pretty much the entire body, with the exception of the face, palms of the hands, and soles of the feet, became involved. Lately the itching has been so severe as to keep him awake all night: indeed, he tells us he is often obliged to stupefy himself with liquor in order to gain a night's rest.

Such are the facts in the history of the case. Now, proceeding to examine our patient, we first observe that the disease is a chronic one. We do not need the history to acquaint us with this fact; any one who has had much experience in this class of cases would immediately perceive the disease to be non-acute. This patch, for instance, can easily be known to have existed some time. We have here numerous old scratch-marks, the result of long and habitual use of the nails. Let me remind you just here that the presence or absence of the evidences of scratching should always claim your attention in the examination of diseases of the skin. Such evidences will decide at once whether the affection under consideration belongs to the class of itching or non-itching diseases. The case before us evidently belongs to the former; even such remote parts of the body as the integument covering the angles of the scapulæ, which are quite difficult to reach, have been attained by long practice on the part of our patient.

As to the localities affected, you will observe that though the disease extends pretty much over the entire body, yet there are certain parts where the process seems to have been more active, as evinced by the greater number of scratch-marks. The regions about the axillæ, for instance, have been very much scratched. Some of these marks are quite florid,—they are recent; others are darker and older. About the nates the disease appears to have been particularly troublesome. We notice here that the corium has become considerably thickened, and many large pustules are scattered over it.

Along the thighs also the scratch-marks are very numerous, and the skin is sprinkled over with crusts, not of dried pus, however, but of blood. We have here, also, broken hairs and torn follicles, from each of which a drop of blood has oozed.

All these appearances result from the scratching; and I dwell upon these marks because they play an important part in the history of the case. Before leaving this point, observe that the inside of each thigh presents the disease in a still more marked form. We have here pustules, scales, pigment-spots, and patches of infiltration, which will endure some time after all active symptoms of the disease have disappeared.

Taking a general view of the case as the patient stands before us, notice the peculiar arrangement of the eruption: plentiful in the axillæ and on the buttocks and abdomen, less so on other parts of the body, notably the sternum. On the palms of the hands and soles of the feet, as well as on the face, absolutely no trace of the affection can be discerned.

The differential diagnosis of the case lies between two diseases: simple eczema, and scabies or "the itch." These two affections are the only ones likely to assume the appearances here presented. Remember that when I speak of scabies as "the itch," it is not merely an itching disease to which I allude, but one of a parasitic nature, dependent upon the irritation and inflammation produced by an insect, the *acarus scabiei*.

A single point shows us almost certainly which of these two diseases we have before us, and that is the arrangement of the eruption. On the one hand, we have it more marked over the axillæ, abdomen, buttocks, and thighs,—all parts of the body well protected with clothing. On the other hand, the eruption is very scanty over the sternum, and does not exist at all on the face, palms, and soles, all of which are localities either greatly exposed to external influences, or which, from their structure, are unfavorable to the morbid process.

In short, the eruption affects those parts of the body best suited to the unhindered development of the itch-insect, and we have before us a case of scabies. Were this eczema, we would have the eruption more irregularly distributed; eczema has no places of election. The diseases in appearance, however, resemble each other closely, and in fact the result of the irritation of the itch-insect is eczema of one form or another; but it is a result, and not the primary lesion. Cases of eczema papulosum are often mistaken for scabies, and the patients reported cured by internal treatment, etc.

The only reliable diagnosis, after all, is based upon the presence or absence of the itch-insect itself, the *acarus scabiei*, which must be carefully sought for in such parts of the skin as it is most likely to be found in. One of these localities is the hand, and particularly the skin on the inside of the fingers. At this point the burrows in which the *acarus* lies are less likely to be torn open, and may also be seen more distinctly than elsewhere. When patients work in strong alkalis, acids, or the like, these

burrows become destroyed, and are then very frequently not found or are altogether absent.

The burrows of the itch-mite are worthy of careful study. They are produced by the insect finding its way under the epidermis and then making a canal or passage which is seen upon the surface as an elevated line or ridge about a quarter of an inch long, usually dark-colored or black, owing to accumulations of dirt and foreign substances which are apt to collect upon the hands.

The burrows are about half a line in width, and vary in length; sometimes they are but a line or two, in other cases they are as much as half an inch long. They are found in greatest number, perhaps several or more, upon the insides of the fingers near the hand, where the skin is thinnest. Here the mites make their habitat, and are apt to remain undisturbed until they have deposited their eggs, when they are known to die in their burrows.

There are very few entire burrows on this man's hands, owing to the fact that the disease is chronic, and the long-continued scratching and tearing to which the skin has been subjected has caused them to become rubbed down, broken, torn, and scraped off, and finally, to a great degree, obliterated. Still, there are some left, and by carefully searching these the insect may be detected and picked out. We need not expect to find a dozen in this hand; we shall be fortunate if we find two or three.

In order to obtain the acarus, we take a needle, and, opening the closed end of the burrow, which is indicated by a black dot, and which is the point where the insect lies, we may be able, if dexterous, to lift it out upon the needle-point. The operation must be performed very carefully, otherwise the wrong end of the burrow may perhaps be picked, and a drop of serum exuding will swamp the acarus beyond all hope of recognition. The parasite, you must remember, is exceedingly small,—scarcely the one-thirtieth of an inch in diameter,—and of a color and transparency almost those of serum itself. You must be careful, therefore, I repeat, or you will almost certainly fail to obtain it.

It is the female acarus which burrows in the way I have described, in order to deposit its ova. The male insect crawls about over the surface of the skin, and may be detected with the aid of a lens by those who are more than usually fortunate. He is exceedingly difficult to find.

Scabies is a very rare disease in Philadelphia, on account of the well-known habits of cleanliness to which our people are accustomed. A comparatively small number of the inhabitants of this city live crowded together in tenement-houses, and bathing is frequent. Besides this, comparatively few emigrants arrive at this port, while in other cities, as Boston and New York, whole ship-loads are frequently emptied into the population, bringing the disease with them and spreading it in all directions.

The consequence is that scabies is much more common in those cities than in Philadelphia, and you will find ten or twenty cases in New York to one here.

I will not give you at this time the treatment of

scabies in general, but merely the plan which we shall pursue in the present instance, which is as follows:

Let me begin by advising you, whatever application it may be of which you make use, not to make it too strong. Were we to employ the officinal sulphur ointment, for instance, in this case, containing as it does four drachms of sulphur to the ounce of lard, we should make the patient's condition worse for the time than before, since an artificial irritation would in all probability be set up. He already has eczema from severe and long-continued irritation of the skin, and any strong application would only tend to aggravate the inflamed skin.

We shall, therefore, in the present instance, make use of the following formula:

R Flor. sulphuris,
Bals. Peruvian., āā ʒii;
Adipis, ʒiv.—M.

This ointment is to be thoroughly worked into the affected portions of the skin every morning and evening for four days. If this has been thoroughly done, the scabies itself will by that time be cured, and there will remain only the artificial eczema produced by the presence of the acarus. This, the cause having been removed, will probably get well spontaneously, nothing more being needed than bathing. You must not expect, in a case like this, that all itching will cease the moment the disease is put an end to. The mere nervous excitability brought about by long-continued sleeplessness and irritation will not at once subside. We shall, however, expect that, when this patient appears before us a week hence, most of the itchiness shall have subsided, and that he shall enjoy a good night's rest.

It will be some time, however, before all traces of the eczematous eruption shall have disappeared, and it may be necessary to hasten this result after a few days by such an ointment as the following, to be applied morning and night, after bathing:

R Acid. carbolic., gr. x;
Ung. zinci ox. benz., ʒii.—M.

ORIGINAL COMMUNICATIONS.

STRYCHNIA IN ATROPHY OF THE OPTIC NERVE.

BY GEORGE C. HARLAN, M.D.,
Surgeon to Wills Ophthalmic Hospital.

AS the value of strychnia in the treatment of amaurosis may still be considered, to a certain extent, *sub judice*, or as, at any rate, its use is by no means so general yet as it might be, the report of a few cases in which it has been given a faithful trial may not be out of order.

Though the records of ophthalmic literature show that strychnia has been used in this disease occasionally and in a desultory way for years, principally by means of applying the powder to blistered surfaces on the temple, or by rubbing it in the form of oint-

ment about the brow, perhaps to Nagel belongs the credit of having, in 1871, reintroduced it, employed it rationally and systematically, and given it a recognized place in ophthalmic therapeutics.

Nagel, in all his cases, administered the drug by subcutaneous injection, and selected the temple as the place of its introduction; and, with few exceptions, all other surgeons who have adopted the treatment have followed the same plan.

Gori, of Amsterdam (*Annales d'Oculistique*, July and August, 1872), gave it as the result of his experience that this treatment might effect decided improvement even in cases where the loss of vision was accompanied by evident anatomical changes, but that the mode of administration insisted upon by Nagel was not essential. To avoid the inconveniences that sometimes resulted from frequent hypodermic injections, he dissolved the nitrate of strychnia in tincture of iodine, and painted it daily on the temple and around the orbit, and claimed that this method was equally efficient.

Dr. C. S. Bull, of New York (*Am. Jour. Med. Sciences*, April, 1873), gives decided preference to hypodermic injection, but thinks it a matter of no importance what point is selected for the operation, and chooses the fore-arm as a matter of convenience.

Dr. Chisolm, of Baltimore, who has contributed several interesting articles on the subject to the same journal, and who was, I believe, the first to call attention to it in this country, began with hypodermic injections in the arm, but was afterwards convinced that identical results could be obtained by internal administration.

A matter of great practical interest is the dose that should be given. This has shown a decidedly upward tendency. Nagel used subcutaneous injections of from one-fortieth to one-thirty-second of a grain, repeated daily or at intervals of one or two days, during periods of from a few days to three or four weeks; but much larger doses seem to be now very generally considered necessary. Indeed, it may be considered to be pretty well decided that the treatment has not had a fair trial in any case in which the remedy has not been pushed to the largest dose that the patient can comfortably or safely bear.

Dr. Chisolm, in his first report (January, 1872), says, "I commence usually with one-sixtieth of a grain, which I gradually increase to one-thirtieth twice a day (by hypodermic injection), in no case exceeding this last amount." In his last article (April, 1873) he gives it as the result of his extended experience that one-half grain daily, administered internally in divided doses, produces the best remedial effects.

He thinks that when these large doses have secured a tolerance, they may be safely continued for months, or may be even still further increased should they lose their effect. He tells us that the maximum dose can be attained in from fifteen to twenty days, but gives us no means of discovering at what time he has found the maximum curative effect to be produced. Dr. Chisolm has not given his cases, but only his general conclusions, and it is to be regretted that he has not been more definite on this point. Though detailed notes of cases make

sadly dry reading, they often make also the most reliable and useful kind of statistics.

In the seventeen cases reported by Dr. Bull, the period of treatment varied from six days to three months, and the maximum dose from the one-fortieth to the one-tenth of a grain of the nitrate, injected in some cases daily and in others every other day. He concludes that when we do not see any improvement after the first three or four injections, not much advantage is to be expected from its use. I am not quite inclined to agree with him in this, though his experience has been much more extended than my own.

In three very successful cases recently reported by Dr. H. Derby (*Boston Med. and Surg. Journal*, November 5, 1874), the periods of treatment were from four to ten weeks, and the maximum dose was in one case one-eighth, and in the other two one-fourth of a grain of the nitrate, injected in the temples at intervals of several days.

In my own cases, sometimes the sulphate in solution and sometimes the alkaloid in sugar-coated granules was given continuously in gradually-increasing doses, until decided symptoms appeared or improvement ceased. The maximum daily dose varied from one-fourth to one-half grain, and the periods of treatment from two to ten weeks. Perhaps the maximum dose might with advantage have been reached more quickly in some of the cases and have been increased in others.

In regard to the mode of administration, my belief is that it is a matter of little moment whether the nitrate, the sulphate, the acetate, or the alkaloid is used, or whether it is injected in the temple or the arm, or given by the stomach, provided the system be brought thoroughly under the effects of strychnia. I would not suspend the use of the drug until a decided effect had been produced, or be disposed to continue it long afterwards unless the improvement in vision still progressed, which has not occurred in any of my cases.

A good deal has been written about the particular conditions of the nerve to which this treatment is applicable; but my limited experience rather confirms the impression derived from the study of the practice of others, that it rests entirely on empirical grounds, and that the ophthalmoscope furnishes no reliable data for deciding whether strychnia is likely to be of use or not. Though it may be said, in general terms, that those cases offer the greatest hope of improvement in which there is least evidence of anatomical change, even this rule is by no means without exceptions, as is shown by the fortunate result in Case V. In this case it was evident, both from the previous history and the ophthalmoscopic appearances, that the condition of the nerve was the result of inflammatory changes.

Only one of my cases belonged to the class to which Dr. Derby calls attention as being particularly amenable to this treatment. I allude to the form of disease called "tobacco amaurosis," or "alcohol amaurosis," or more comprehensively, and perhaps more correctly, as those who drink or smoke to great excess are likely to be generally regardless of sanitary laws, "amblyopia ex abusu."

Dr. Schoen (*Annales d'Oculistique*, September and October, 1874), considering the pathology of these cases to be, in the commencement at least, retinal anæsthesia, has prescribed santolin, and claims that it has given him even better results than strychnia.

In the mysterious form of amblyopia that is often met with in hysteria I have tried strychnia only once, and with no other effect than a violent headache, a decided increase of "nervousness," and general discomfort. I have not thought it worth while to try it in cases where vision was entirely lost, or where a high degree of amblyopia had existed for a long time; nor have I had any experience, as yet, in its use in amblyopia from disuse, though others have obtained excellent results in the latter class of cases.

As the best way of showing the progress of the cases and its relation to the increasing dose, I give the following extracts from the hospital records.

Case I.—J. F., a day-laborer, aged 62, stated that his sight had been failing for two years, but that he had found out, by accident only, six months before, that the left eye was quite blind. In the right eye there was vision of $\frac{2}{80}$ (that is, he could distinguish No. 80 only of Snellen's test-types at twenty feet, instead of No. 20, and consequently had only one-fourth the average acuteness of vision). In the left eye there was complete white atrophy of the disk, and no perception of light. In the right the atrophy was evident, but not so advanced. There was some central limitation of the field of vision. The pathology of the case was obscure. It seemed to be one of simple progressive atrophy, as there was no sign of local inflammation and no history of cerebral symptoms.

Treatment was commenced, October 20, by one-twenty-fourth grain of strychnia sulph. given internally three times a day. This was continued until November 7, without improvement.

November 7.— $V = \frac{2}{80}$; ordered four-twenty-fourths grain daily.

November 17.— $V = \frac{2}{80}$; ordered three-twelfths grain daily.

November 26.— $V = \frac{2}{80}$? (doubtful); ordered three-twelfths grain daily.

December 3.— $V = \frac{2}{80}$? (doubtful); ordered three-twelfths grain daily.

December 15.— $V = \frac{2}{80}$ distinct, and some letters in XXX.

December 22.—Had continued to take three-twelfths grain daily, but without further improvement; and, though there was no muscular spasm, he had a good deal of headache and malaise, and treatment was discontinued.

Case II.—O. M. was entered on the record as a case of "tobacco-amaurosis." He was a shoemaker, and had been in the habit of smoking a pipe, while at work, the greater part of the day. His sight had been gradually failing for about nine months, and for some weeks he had been obliged to give up his work entirely. The external appearance of the eyes was natural, except that the pupils were slightly dilated and moved sluggishly. His vision was only $\frac{1}{100}$ in each eye, little more than enough to enable him to go about without assistance. The ophthalmoscope showed nothing abnormal but a slight blanching of the disks.

March 20.— $V = \frac{1}{100}$; ordered strychn. sulph., three-thirty-seconds grain daily.

March 31.—No improvement. Ordered strychn. sulph., four-thirty-seconds grain daily.

April 6.— $V = \frac{6}{100}$ in R, $\frac{6}{80}$ in L; ordered strychn. sulph., five-thirty-seconds grain daily.

April 13.— $V = \frac{6}{80}$ in each; ordered strychn. sulph., three-sixteenths grain daily.

May 13.— $V = \frac{6}{80}$. Had omitted the medicine for some time. Commenced again with three-twenty-fourths grain daily.

May 18.—Ordered three-eighths daily. May 21, three-sixteenths. May 27, four-sixteenths.

May 29.— $V = \frac{4}{80}$? Ordered to continue four-sixteenths, though there was slight spasm. June 1, five-sixteenths.

June 8.— $V = \frac{4}{80}$ distinct. Ordered three-eighths grain daily.

June 15.— $V = \frac{4}{80}$; ordered one-half grain daily.

July 1.— $V = \frac{2}{80}$; ordered to continue.

July 6.— $V = \frac{1}{20}$, which enabled the patient, with convex glasses, to return to his work without difficulty. The improvement in vision in this case is represented mathematically by the difference between the fractions one-twenty-fifth and one-half.

Case III.—M. O., aged 22, could see to read until she was fifteen years of age, and then her vision gradually failed. She was excessively nervous, and subject to "spells" which, from her account, seemed to resemble catalepsy.

The ophthalmoscope showed bluish-white atrophy of disks, and indications of old choroiditis. Strychnia was administered, commencing with one-twenty-fourth grain three times a day, and gradually increased to one-twelfth, when symptoms of poisoning appeared, and treatment was suspended at the end of two weeks. No improvement.

Case IV.—C. K., 33 years of age, stated that six or seven years before, he had had typhoid fever, and had been subject to frontal headaches since; that he had occasional attacks of dimness of vision immediately after the sickness, and that about one year ago the dimness commenced to increase rapidly, and became permanent. When he came to the hospital there was barely enough sight left to enable him to go about the streets alone. In the right eye there was entire obliteration of the inner side of the field, and he could count fingers, with difficulty, in the outer half. With the left he could distinguish the letters of No. 70 at one foot in the centre of the field, and only No. 200 at either side. The ophthalmoscope showed decided blue atrophy of the disks, though the retinal vessels were not very much diminished in size. Treatment was commenced July 9 with one-tenth grain daily, the dose being gradually increased at intervals of a few days.

August 24.—He had been taking two-fifths grain daily for five days, and his vision had increased in the left eye from $\frac{1}{70}$ to $\frac{1}{40}$? Not much improvement in the right.

August 31.—Had been taking one-half grain daily since the 27th, without further improvement. As he complained of headache and muscular spasm, treatment was discontinued.

Case V.—E. H., about 20 years of age, the daughter of a farmer in the interior of the State, had been in the hospital more than a year before. She had, at that time, well-marked optic neuritis, with engorgement of the retinal vessels, but without "choking" or decided swelling of the disks. The neuritis was evidently of cerebral origin, as it was accompanied by paralysis and other unmistakable symptoms. Under the use of mercurial inunction, iodid. potass., and quinine and iron, her vision had risen from $\frac{1}{200}$ to nearly $\frac{2}{80}$ when she was discharged. At the time of her re-admission there was still slight hemiplegia, and her vision had fallen to $\frac{4}{80}$. The retinal vessels were contracted, the disks were whitened, and there was perceptible atrophic cupping. Strychnia was administered, in gradually increasing

doses, until it had to be discontinued on account of the sudden appearance of alarming symptoms of poisoning. When she recovered she was delighted to find that her sight had greatly improved, and that she was able, with comparative ease, to read a letter from home, which had been utterly impossible before.

Five months afterwards, she wrote that the improvement in her vision had been permanent, though her other symptoms had grown much worse. The following record is from the notes of the Resident Surgeon, Dr. J. A. Lippincott, who watched the case with great interest and care:

"June 5, $V = \frac{4}{80}$; ordered strychnia sulph. three-thirtieths grain daily; June 12, ordered three-twenty-fourths grain daily; June 16, three-twentieths grain; June 22, three-sixteenths grain; June 27, three-fourteenths grain; July 2, three-twelfths grain; July 8, threenths grain: still no improvement.

"July 12, $V = \frac{5}{80}$; ordered three-eighths grain daily.

"July 16, $V = \frac{6}{80}$; ordered three-sevenths grain daily.

"July 21, $V = \frac{8}{80}$; ordered three-sixths grain daily.

"Complains of inability to speak distinctly, from stiffness of the tongue.

"July 24.— $V = \frac{14}{80}$. Taken in the evening with spastic contractions of the voluntary muscles, accompanied by delirium of an hysterical character. Stop strychnia July 31.

"The symptoms above mentioned continued for the past week, intensified at night, and requiring large doses of morphia and chloral to subdue or moderate them. Chloroform by inhalation was tried, but with merely transient benefit. This morning the patient is rational, and screamed with delight on finding herself able to read the address and contents of a letter that was handed to her. Can read No. 3 Snellen with ease, and No. 2½ with some effort. Resumed the strychnia sulph., in doses of three-sixteenths daily.

"August 8.—No further improvement; discharged."

A point of great interest in this case is the fact that improvement did not commence until the patient had been under treatment more than a month and the dose had been increased to three-eighths grain, and did not reach its maximum until she had been brought thoroughly, and, as we feared, dangerously, under the influence of strychnia.

DISLOCATION OF THE HEAD OF THE FEMUR FORWARD ON THE PUBIC BONE.

BY J. R. SHELLENBERGER, M.D.,

Mt. Airy, Philadelphia.

THE accident occurred in a gentleman aged 64 years, in good health, and with well-developed muscles. He stood by the side of a rapidly-moving train, and with his left hand caught the iron railing, and at the same time put his left foot on the step. He was violently swung upon the platform, and, recovering himself, found his right foot turned outward, and judged at once that dislocation had taken place.

I saw the gentleman twenty minutes after the receipt of the injury, and found him entirely unable to walk, and in great pain. On examination, the limb was three-fourths of an inch shorter than the left, the foot and knee turned outward. The head of the femur could be distinctly felt upon the ramus of the pubes, outside of the femoral artery, both being very prominent.

The reduction of the case was extremely difficult.

The patient was thoroughly etherized, and three separate times during the day manipulation and the pulleys were tried, but both failed, though most persistently and conscientiously applied. Twenty-three hours after the accident, after a full dose of morphia and a good sleep, it was reduced by manipulation alone, Drs. Agnew, Hunt, Darrach, and Cooper having all been called in consultation.

The patient was placed upon a table, and his hips fixed by binding him to it with a folded sheet. Then, by flexing the thigh until the trochanter major rested just beneath the anterior superior spinous process of the ilium, a fulcrum was made of the latter bone and the head pried out from the pubic bone, when, by a sudden inward rotation, the head glided down; but, instead of entering the acetabulum, it went around that cavity upon the dorsum of the ilium. From this position, however, it was easily dislodged by flexion, outward circumduction, and outward rotation, when it readily slipped into the socket. No inflammation followed, and the patient at present writing, three weeks after the accident, is doing remarkably well.

Prof. Gross says, "The pubic dislocation is an extremely uncommon one, and might, therefore, almost be classed among the rare forms of the accident." Rare indeed, when surgeons of forty years' experience have not met with a case of the kind!

Sir Astley Cooper's experience was that out of twenty cases of dislocation of the hip, twelve were on the dorsum of the ilium, five in the ischiatic notch, two in the foramen ovale, and but one on the pubic bone.

ARSENIC AS A REMEDY FOR ASTHMA.

BY GEORGE ROBERTS, M.D.

IN the *American Journal of the Medical Sciences* for January, 1874, attention was called to the use of arsenic in asthma. I have had under my care the past summer a case of long suffering,—a lady who had moved to Wisconsin, Minnesota, and finally to Nebraska, to obtain relief by the change of air.

Mrs. H., aged 50 years or more, Norwegian, asserted that she had not been able to rest in the recumbent posture for more than a year. It was midnight when I called, April 1. The paroxysm was relieved by chloroform,—the patient sleeping.

The following day Fowler's solution was administered, gtt. v three times a day, and continued with no bad symptoms. After the third day the patient was so much relieved as to be able to attend to her household duties.

Having a troublesome cough, a mixture containing potass. cyanid. and morph. acet. was given, which relieved her.

It is now Nov. 23; the patient is robust and apparently well, with no tendency to asthma. She occasionally has a slight cough.

CREIGHTON, KNOX Co., NEBRASKA.

A WRITER in the London *Lancet* asserts that the constant use of powdered charcoal as a dentifrice will produce a blue line on the gums closely simulating that of lead-poisoning.

NOTES OF HOSPITAL PRACTICE.

PHILADELPHIA HOSPITAL.

SERVICE OF DR. H. C. WOOD.

Reported by JOS. BERENS, M.D., Resident Physician.

CEREBRAL HYPERÆMIA.

GENTLEMEN,—I will occupy the remaining few moments of my hour by saying a few words about a case that terminated fatally in the hospital a few nights since. The notes of the case are these:

Jane McG. was brought to the hospital in the evening of the 8th of October. She had spent the previous night in a station-house, where, during her stay, she had had a number of epileptic convulsions. Her history is that of a hard drinker and degraded character generally. It was also ascertained that she had never been subject to epileptic attacks previously. When first seen in the ward, she presented the appearance of a person in a drunken stupor: face deeply flushed, carotids pulsating violently, head hot, eyes staring, pupils dilated and not sensitive to light, conjunctiva almost without sensibility, pulse 112, hard, bounding, and full, respiration 33 to 36 per minute, deep, and somewhat stertorous in character, temperature 106° . Stupor so profound that she could barely be roused to make an ineffectual effort to put out her tongue, which was dry and brown. There was a contused wound of the scalp, two inches long, and penetrating to the skull, which was not fractured. She received two drops of *ol. tigllii*, and, this not proving effective in three-quarters of an hour, the dose was repeated. During the next hour she had five epileptic convulsions, which were very violent, lasted about a minute, and were not followed by anything akin to sleep except in the first instance.

An hour after the second dose of *ol. tigllii*, it had produced no evacuation, and a large injection of soap-and-water was given. This was followed in a few minutes by the discharge of an enormous amount of fæces. Ice to the head, mustard to the feet, and turpentine stupes were now applied, and she was given sixty grains of bromide of potassium. In twenty minutes the temperature had fallen to $104\frac{3}{4}^{\circ}$, but there was no corresponding amelioration of the other symptoms. During the next two hours she had eleven convulsions, all very violent. Another dose of sixty grains of bromide of potassium was administered. At the end of the next hour there had been four more convulsions, but the pulse had fallen to 93, and the temperature to $102\frac{1}{2}^{\circ}$; in addition, the patient began to perspire freely. During the following hour the pulse fell to 90, and was much softer and more normal in quality. The general symptoms also lacked in a marked degree the sthenic type which had characterized them at first; the patient seemed more conscious; there was but one convulsion. A thirty-grain dose of bromide of potassium was administered. During the next hour the temperature fell to 101° , the pulse remaining at 90. The patient still perspired copiously; there was but one convulsion.

The following hour was marked by a general change for the better; pulse 88, temperature 101° , respiration quiet, perspiration much less excessive. Pupils and conjunctiva both quite sensitive. At 5 A.M. (Oct. 9), an hour afterwards, the temperature was 100° , and the case seemed to be progressing favorably. Fifteen grains of bromide of potassium ordered every two hours, with continuation of ice to the head. At 7 A.M. the temperature was 102° , pulse 98, skin dry. Ordered a weak milk-punch, with other treatment. At 2 P.M. the pulse was 120, respiration 44, temperature $104\frac{1}{2}^{\circ}$.

At 7 P.M., temperature 105° , pulse 180, respiration 60.

At 12 M., temperature 106° , pulse 160, respiration 70.

Patient in a reeking sweat, which saturates even the blankets on which she lies.

At 12.15 P.M., patient died without a struggle.

Now, what was the matter with this patient? In convulsions accompanied by unconsciousness, the cause may be set down as cerebral. These convulsions were not hysterical, as the temperature was too high; for the same reason they were not due to chronic epilepsy, as is also shown by her previous history; and, on the same authority, we are justified in saying they were acute; the temperature also excluded the diagnosis of uræmia and of alcoholic poisoning, for it has been repeatedly and satisfactorily proved that in both of these the temperature is lower than normal. The convulsions, however, were undoubtedly epileptiform, and in such convulsions accompanied with high temperature the cause is usually found to lie in the onset of an exanthematous or blood-disease, or in an inflammation about the brain.

Thus, when she first came in, the question lay between cerebral inflammation and intense systemic fever, and to decide which of these was all that was necessary for treatment. In this connection, gentlemen, I wish to impress upon you the necessity of learning to regulate your treatment by general principles, and not to hesitate to act in the absence of a definite diagnosis. All of you, in the course of your future practice, will meet with cases where an exact diagnosis is impossible, yet where prompt and efficient action is requisite to preserve life. Under such circumstances you must use your common sense in adapting the therapeutic weapons at hand to the emergency before you, and feel no trepidation because you cannot fix a name to the train of symptoms you are called upon to combat.

But in this case what was to be done? If the case was one of blood-poisoning, the patient ought at once to have been put in a cold bath, or subjected to some other mechanical means for withdrawing heat, as this should always be done in cases of exanthematous diseases with severe nervous symptoms, when the temperature is above 105° . If the case was one of acute cerebral inflammation, bleeding would have been the proper course, and of very necessity this would have lowered the temperature. But here is a dilemma. If in the high temperature of exanthemata we bleed, the chances are that we will kill our patient. If, on the other hand, the same temperature exist in cerebral hyperæmia, and we *do not* bleed, the patient will probably die. But convulsions in the adult are rare in exanthemata; in addition, there was the wound of the head, which indicated a possible cause of inflammation. Moreover, the pulse is stated to have been hard and full,—not the full gaseous pulse of a blood-disease, but the full strong pulse of intense inflammation. Unfortunately, I did not see the patient until the day after her admission, when it was too late for any treatment. If I had seen her when she came in, I perhaps would have bled her. And, gentlemen, once you make up your mind bleeding is the proper thing to do, especially in such a case, bleed for *effect*, and not by *quantity*. Take twenty, thirty, or forty ounces, till what you desire to effect is accomplished. In all cases of intense sthenic inflammation, as of the brain, the peritoneum, etc., if you do not bleed at once and thoroughly, you will often lose patients whom you might have saved.

The brain before you is from the case we have just been discussing. You will observe here, what very often happens, that even the most intensely-marked cases of cerebral hyperæmia often leave comparatively few post-mortem traces behind them. Here the brain-substance seems perfectly normal; the meninges also show but little congestion, except in one place, on the anterior left lobe, in a position on the other side of the skull from and opposite to the wound of the head. The intense

congestion here indicates that this has been one of those cases where the shock received at one point on the head has been transmitted and expended itself at a point directly opposite.

COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

SERVICE OF PROF. WILLARD PARKER.

Reported by J. M. HARVEY, M.D.

CASE I.—A. B., aged 55, has tumors in different parts of his body, on back, arms, knees, and feet. His general health is and always has been good; never had any disease; he knows of nothing to cause this trouble. He says he cannot move his toes; has lost the power of voluntary motion in them.

This case, gentlemen, is a very unusual one. The first question is, What kind of tumors are these? All tumors are divided into two classes,—benign and malignant. To which class do these belong? They are not cancerous or malignant, they are benign tumors.

The man is healthy; he has no syphilitic or any other taint; and these tumors have existed for five or six years, giving rise to the natural inference that they are benign. Such inference is not, however, always correct. A patient once came to me with a tumor which he had had for nineteen years. It gave him no trouble until within six months of my seeing him, when it commenced to be painful. I removed it, but the tumor returned again; it became malignant after having existed as an apparently benign tumor for nineteen years.

Next comes the histological test. What is the character of these tumors? Are they bone, fibrous, or cartilaginous? I have never seen a case precisely like this. The tumors are callous,—as hard as if they were fibrous in their character. I remember the case of a stage-driver who had forty or fifty tumors of a fatty nature on different parts of his body, while his general health was good, and he lived with his tumors on him until he was eighty years of age, and then died of something else. There is another kind of tumor, called neuroma, which may be diagnosed by pressure upon it, producing a peculiar sensation similar to that which is felt when the "crazy-bone" is struck.

The tumors in this man's case do not yield such sensation, and are probably fibrous in their character.

Now, in relation to diagnosis: first, these are tumors; second, they are benign; third, in regard to their histology, I cannot say until a portion is put under the microscope. My advice is to leave them alone for the present. The man has a good appetite, sleeps well and feels well. If they should pain him, there is no objection to his using a blister; but, as blisters are out of fashion now, he can use a little iodine as a counter-irritant.

Case II.—A little boy 8 years old, with a tumor on his neck. Gentlemen, here, you observe, is another tumor. Is it solid or fluid? It is fluid. You observe the little fellow is pallid; he has not enough red corpuscles in his blood. His parents are healthy. His father does not smoke, and in this respect is a very sensible man. Many a poor child has been sent to his grave by tobacco. There is no man whose system is saturated with tobacco and rum who can have healthy children. If a man must smoke, he ought to have sense enough to go out in the open air, and not live and sleep in a room full of poisonous tobacco-smoke. A man is not fit to be called a man who has to take a pledge to keep from using tobacco or rum. I use neither, but I have taken no pledge except the pledge to do the best I know for myself.

That tumor has fluid in it. You have got pus there.

There is not force enough in the boy's system to get up an inflammation. If the little fellow had roses in his cheeks, that tumor would not be there at all. The diagnosis of Dr. Janeway that it is a cold abscess I confirm fully. I remember of having as a student a lesson on the diagnosis of pus by its fluctuation. An old doctor from the country said in the hospital where a tumor was being examined, "You city fellows don't think a country surgeon knows anything, but you are mistaken; you will find as good brains in the country as anywhere. There is pus in that tumor there, deeply-seated pus." The others laughed in derision, but he said, "I tell you there's pus there." One of the surgeons cut down carefully, but did not find any pus. "Give me the knife," says our country friend, and, plunging it in deep, the pus squirted out.

I have a few things more to say pertinent to this case. That little fellow should be turned out to pasture in the country, where he could browse and have plenty of milk and fresh air. The little fellow is too much shut up; too much confined to the house and school-room, where the atmosphere is bad.

There is another thing I want to refer to. One of God's greatest and best gifts which come down to us is the sunlight. No animal or vegetable can be well and thrive unless it gets the sunlight. Never build your house on the north side of a hill; do not surround your house with trees, but locate yourself so that the sun can get at you. The effect of sunlight upon man has been tested by experiment. The barracks of a large foreign city were arranged north-and-south. The soldiers on the north side were fed, clothed, and placed under exactly the same conditions as were those on the south side. Would you suppose there would be any difference in the death-rate? Do you suppose the death-rate on the north side would be greater than on the south? The death-rate was three to one; that is, for every one on the south side there were three on the north side. There was nothing to ascribe the difference of that death-rate to except that there was sun on the south side and none on the north.

Gentlemen, I will give you some more information. This very day a gentleman gave me an account of a very interesting case. You know at the present time the world is crazy on beef-steak. You would suppose that the best service a man could render his Maker was to eat beef three times a day. If they don't eat beef, they take beef-tea, which is a nasty, dirty mess. Old-fashioned beef-soup is good, and I like it very well, but this beef-tea made out of extract of beef is nasty, muddy-looking stuff. Take a child who has scarlet fever and the albuminuria which accompanies it; what kind of food would be best for him? If you had a patient with Bright's disease, what kind of food would you give him? You would give vegetable food,—substances that do not contain nitrogen. Why? Because nitrogen is excreted by the kidneys in the form of urea and uric acid. Suppose the kidneys were sick, would you impose work upon them? You would spare them. When you feed your patient, who has albuminuria, with beef which contains nitrogen, you increase the function of the kidneys, and this is just what you should not do. If you have a diseased organ, the first and most important thing is rest. Well, this case referred to is a little boy, now nine years old. When five years of age, he commenced self-pollution. Though he had been punished again and again, and every expedient resorted to for the purpose of making him break off this practice of masturbation, it was of no avail. On careful investigation, it was found that the boy had been in the habit of eating tenderloin for breakfast, tenderloin for dinner, and tenderloin for supper. He had eaten three tenderloins a day, thus living on nitrogenized diet. The gentleman was a scientific man, and he looked at the urine

and found it loaded with urea and uric acid. The boy was taken off this animal food and put on vegetable diet, and in less than two months he had no desire for and consequently discontinued the fearful practice referred to. This shows you how important it is to look into these things. I believe there is many a case of epilepsy due entirely to the practice of eating too much animal food. I tell you these things now that you may put them in your memorandum and keep them, as they are important practical hints which you cannot get from your text-books.

TRANSLATIONS.

MEDICAL PROPERTIES OF CANTHARIDES.—Dr. Alessandro Cantieri contributes to *Lo Sperimentale*, October, 1874, an important article upon cantharides. Experiments performed upon various animals (dogs, rabbits, frogs) lead him to the following conclusions:

1. Cantharides introduced into the economy alters the blood-mass, disintegrating and contracting the globules if placed immediately in contact with them, and contracting them alone if the contact is only made through absorption.

2. It diminishes the contractile force of the heart and the vascular walls, and hence lessens the arterial tension. It augments the frequency and rapidity of the cardiac movements, increases the temperature, causes loss of nutrition and general enfeeblement,—phenomena which indicate a real and especial fever.

3. Cantharides produces hyperæmia by blood-stasis in the various organs, and, if the dose is large, gives rise to true inflammations. According to these experiments, it is certain that it excites hyperæmia of the brain and spinal cord; softening to a slight degree in the former, but more decided in the latter. This softening in the cord is more marked in the dorsal and lumbar enlargements, particularly in the latter, where it may give rise to paralysis of the lower extremities. This is observed in dogs, rabbits, and frogs; in the latter there occurs, besides, entire loss of reflex activity.

4. The meninges are the seat of hyperæmia always more marked at the base of the cranium, and particularly where it supports the medulla oblongata. It is this, probably, which, in dogs and rabbits, gives rise to the great frequency of respiration and acceleration of the circulation, with occasional intermittences, which have been observed.

5. The hyperæmia always brings about inflammation of the genito-urinary apparatus, either desquamative or parenchymatous nephritis, with presence of albumen in the urine. It causes venereal excitement, and may give rise to abortion.

6. Cantharides administered internally causes, besides all the morbid alterations mentioned, a true gastro-enteritis, with extensive congestion and ulceration of the gastric mucous membrane, accompanied by a secretion of yellow mucus. Sometimes, when injected into the veins, it does not cause ulceration, but congestion of the gastro-intestinal mucous membrane, with diarrhoea. This occurs frequently in dogs, rarely in rabbits.

These conclusions stated, it remains to apply them in practical medicine; and this is attempted by Dr. Cantieri. His experiments and observations, which have been made on a great number of patients and with a great deal of care, throw considerable light upon the subject. His very conscientious study of the subject terminates by indications for the employment of the vesicatory, and finally by the following conclusions:

After having remarked that blisters should be allowed to remain applied during as short a time as possible, that

they should not be made use of in the case of nervous and delicate subjects, in dropsical subjects, particularly in those cases where the anasarca is dependent upon renal disease, in infectious diseases, cholera, or chronic cardiac affections, he adds that the application of blisters of cantharides can only be of use in medicine for their rubefacient action in simple venous hyperæmias or stases, as in those caused by insolation or abuse of alcohol, in simple cardiac affections, and in other diseases of the same kind.

If Dr. Cantieri gives us these indications, it is because he has recognized that cantharides, applied as a blister, debilitates the action of the heart and of the vessels, instead of exciting them; that other stimulants, administered internally, are much preferable; that it causes hyperæmia of the kidneys, active and passive; and that in diseases of these organs it should be entirely banished from use, as well as in cardiac affections,—above all, where albumen is found in the urine. The blister should not be employed, he remarks, in the substitutive method, since, besides its local action, it possesses an absorptive, which may have grave results. It may be employed as a rubefacient in the cases above mentioned, but sinapisms and hot foot-baths present fewer inconveniences.

In acute diseases, in typhoid and other infectious fevers, where adynamia and ataxia prevail, its use should be guarded, since by absorption of the principles of the cantharides, which alter the blood-globules and diminish the contractile force of the heart, infection is piled upon infection. In addition, cantharides alters the cerebro-spinal axis, and therefore brings about disorders in the vital functions depending upon it. It augments inflammations and produces blood-stasis, for it arrests the contractility of the vascular walls and paralyzes the vaso-motor nerves, or rather is active in changing the products of inflammation by altering the crasis of the blood. Finally, it favors cardiac collapse, in place of preventing it, as is generally believed.—*Bull. Gén. de Thérap.*, November 30, 1874.

THE WET SHEET IN SCARLATINA (*The Lancet*, November 14, 1874).—Mr. John Taylor believes that the wet sheet affords the best *external* means for eliminating scarlatinal poison and preventing destructive sequelæ. It promptly suppresses pyrexial heat and itching; produces sleep, with a soft secretive skin, more or less continuously; and enables the digestive organs to accomplish that great desideratum in the treatment of scarlatina,—viz., absorption of highly nutritious food. It may be repeated, on the recurrence of the febrile paroxysm, two, three, or four times in twenty-four hours, the patient remaining enveloped from half an hour to an hour. Mothers and nurses who have witnessed its efficacy are most earnest in its repetition. His plan of procedure is to immerse a nightgown, slit up at the front, in hot water (half a pint to a pint), pure, or medicated with a drachm or two drachms of tincture of capsicum, or in the infusion of three or four pods; or in mustard-water, the clear supernatant fluid from a tablespoonful of mustard to a pint of water; extending the gown over the feet by means of a towel immersed in the same fluid, both to be well wrung out and suddenly applied, and the patient quickly packed in two blankets previously placed on the adjoining sofa or bed; another blanket, or two pillows, or an eider-down quilt, covering all.

He does not intend this treatment to exclude the ordinary forms, but believes that if it is judiciously incorporated with them it will be the means of saving many lives that would otherwise be lost, and of diminishing the duration and severity of the sequelæ.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, DECEMBER 26, 1874.

EDITORIAL.

PROF. ERICHSEN'S ADDRESS ON AMERICAN SURGERY.

WE suppose that there is not a reader of this journal who has not been gratified at the hearty recognition by Mr. Erichsen of the true position of American surgery.

Considering the brief stay which was made by the Professor, his assertions as to facts are singularly correct, as his deductions are certainly very sagacious. There are, however, a few points which a longer tarry would have given him more light upon. First among these we note, "With the exception of hospitals for the diseases of women, I know of no special hospitals in any of the large American cities." Confining our attention to Philadelphia alone, there are the Wills Hospital for Diseases of the Eye, and the Orthopædic Hospital, both of them very active and very flourishing institutions. Moreover, the University Hospital may be looked upon as a congeries of special hospitals, since it is largely composed of special wards, attended by specialists, for diseases of the eye, of the ear, of the skin, of women, and of the nervous system.

Antiseptics are probably used in this country more extensively than Mr. Erichsen believes them to be: at least, so some of our prominent surgeons state.

The museums of this country are not in the "undeveloped" condition which Mr. Erichsen represents them to be in. So far from those of this city being

inferior to those of Boston, that of the University of Pennsylvania alone is much superior to anything of the sort in the country north of Washington, whilst the museum of the Pennsylvania Hospital is itself probably equal to the Boston collection. Unfortunately, the University museum was packed up, *in transitu* from the old to the new building, during Mr. Erichsen's visit: otherwise he would probably have been as much pleased at its richness as he was with other features of American surgery.

WE copy from the Annual Report of the State Hospital for Women and Infants:

"The Board desires to correct a misapprehension which, doubtless, exists to some extent, that the object of the institution is the care and shelter of the deliberately vicious; but the following provisions of the By-Laws will correct that error:

"'No applicant shall be received unless she be clean and free from contagious disease.' 'No unmarried woman shall be admitted to the Lying-in Hospital except for her first confinement.'"

We commend most highly this charity, whose object is to rescue from a life of sin and infamy those who have been led astray. There have been seventy children born in the institution, and as yet no death of a patient.

THE *London Doctor* says to its subscribers who are in arrears, very emphatically, Pay up! and threatens, first to publish the names in its own columns, then to hand them to the protective trade associations, so as to ruin their credit, and finally to sue all parties.

RULE OF THREE.—A problem for any one interested in institutions adhering to the mediæval system of medical instruction: Harvard Medical College, first year, new class, 29; second year, new class, 51; third year, new class, 106. What will the tenth class be?

CORRESPONDENCE.

MEDICAL DOINGS IN BALTIMORE.

AT the regular meeting of the Medical and Surgical Society of Baltimore, held on the 10th instant, Dr. Morris related a case of *placenta prævia* to which he was called by the attending physician. The lady was only eight months advanced in pregnancy, and had had several floodings. At the time of confinement delivery was effected with forceps, and Dr. Morris was called in on account of *adherent placenta*. The doctor said he had seen a number of these cases, but never one like this. The placenta was nearly all detached,

but a small closely-adherent portion, which they were unable to remove, was firmly attached to the posterior surface of the uterus. After delivery there were several gushes of blood, but the injection of liq. ferri sulph. checked the flow. The lady died three days after, from anæmia.

Dr. Uhler asked whether transfusion would not have been useful.

Dr. Morris said that it would have been justifiable, but that he had read all the cases of transfusion reported in the journals during the last year, and he doubted the efficacy of the proceeding.

Dr. Evans was of the opinion that if loss of blood was the cause of death, transfusion would have been eminently proper.

Dr. Erich thought that the absence of a person with the necessary experience and instruments was to be deplored, and hoped some one would prepare for emergencies of this kind. Dr. Morris was right in regard to the failure of cases of transfusion in which lamb's blood was used, but with human blood several cases have succeeded.

Dr. Seldner had seen the operation performed several times in Vienna, but it had failed in every instance. Hebra performed it in a case of burns, and Späth tried it after Cæsarian section.

A number of members then engaged in the discussion, touching more especially upon the kind of animal from which the blood was taken and the class of cases likely to be benefited by the operation. It was thought to be worthy of trial in cases of hemorrhage, but useless in phthisis and other debilitating diseases, especially as it could not be used until all other means had failed.

Dr. Morris read an interesting paper on "*Pelvic Cellulitis*." He said the disease was known to the ancients, and was described by Paul of Ægina, but that we are most indebted to Doherty, of Galway, and Churchill, of Dublin, for a careful investigation of the subject. Sir J. Y. Simpson pursued the inquiries, and much enlarged our knowledge, and to him we owe the name now used. It has received various names by different authors,—viz., abscess of uterine appendages (Churchill); parametritis (Virchow); perimetritis (Byford); peri-uterine cellulitis (Thomas). The doctor proposed to follow Simpson in his description of the disease, but he should be compelled to differ with the authorities on several points. First, in regard to frequency. In a practice of twenty-nine years, embracing over two thousand cases of labor, he had met only two cases in which the symptoms were as described. He had met a number of cases of pelvic peritonitis, and had at times been almost disposed to agree with those who deny the existence of cellulitis. As to the seat of the disease, it may be in any of the parts surrounding or adjoining the uterus. McClintock says it is usually in the broad ligaments. There is an immense amount of cellular tissue in the pelvis upon which the disease can vent its force. The products of the inflammation are serum, pus, coagulable lymph, and sloughing cellular tissue. The disease may be found in mar-

ried women who are childless, and even in virgins, but it is usually met with from three to ten days after delivery. The English do not separate pelvic cellulitis from psoas, iliac, and peri-rectal abscess; while the French, with Nonant at their head, recognize only inflammation of the broad ligaments as entitled to the name. But few cases are met with uncomplicated by disease of the cellular tissue of the broad ligaments. Parturition, abortion, excessive sexual intercourse, cold, blows, etc., may act as causes of the disease. He thinks pessaries may with great propriety be added to the list (case in the October number of *Obstetrical Journal*, produced by a pessary). Parturition and abortion produce about two-thirds of the cases, but it may result from any operation on or injury to the pelvic organs. Dr. M. has seen great constitutional disturbance and inflammatory fever result from the introduction of a tent. It may occur at all ages; and even in the male it may follow operations on the pelvic contents. There is such a case reported in the *Lancet* for November 21. In regard to the seat, McClintock found the right iliac region affected in twenty-seven cases, the left in thirty-four, both in three, and eight supra-pubic. The disease may usually be recognized by vaginal or rectal examination, making pressure with the other hand upon the hypogastrium. The principal guides are pain, tenderness, and constitutional disturbance. Hæmatocele, fibrous tumors, and pelvic peritonitis are the only affections likely to furnish any difficulty of diagnosis. He is convinced that many cases of pelvic peritonitis are called cellulitis. It rarely becomes chronic, as chronic pelvic abscess is one of the results rather than one of the stages of cellulitis. Suppuration may occur in a few days, but usually does not for two or three weeks. The prognosis is usually favorable, so far as life is concerned. Simpson says that tubercular disease of the peritoneum may be set up. Treatment: Before effusion, leeches to hypogastrium, perineum, and anus; warm fomentations, opium, and sedatives; aconite to quiet heart's action; hypodermic injections of morphia; anodyne suppositories and absolute rest. He is not much in favor of mercury, as it is likely to do harm in scrofulous women. Dr. Hintze, of this city, gave mercury and opium, in cases of parturition, to forestall and arrest inflammatory action. Blisters, as a general thing, are not advisable; and purgatives should never be used; the rectum should be unloaded by enemata. The diet should be light and altogether fluid, as milk, beef, broth, etc. After suppuration, the aspirator can be used advantageously.

Dr. Erich said that Dr. Morris laid great stress on pessaries producing the disease. Would he condemn them on that account?

Dr. Morris replied that pessaries can produce it, but not usually; he would not condemn them for that reason only.

Dr. Montmonier saw a case of cellulitis in which part of the pus was evacuated below Poupart's ligament, the other portion pointing in the perineum.

Dr. Lynch has never had a case of post-partum cellu-

itis, but had had two cases of ante-partum. In the first case he was called to attend a woman supposed to be in labor. Upon making an examination, he found a swelling to the left of the os, and there was a discharge of an immense quantity of pus. He gave opium and washed out the vagina. The woman was confined two weeks afterwards, and did well. The second case was a similar one. He was called to attend a woman supposed to be in labor. On examination, a tumor was detected on the left side of the cervix. He gave full doses of opium, and the woman went on for three weeks, when labor came on, and, during a severe pain, the tumor burst, and the vagina was flooded with pus. He had to perform craniotomy. The woman got well.

Dr. Seldner remarked that, in Vienna, Prof. Braun usually punctured these abscesses: in some cases, through the vagina; in others, through the abdominal walls.

The Medical and Chirurgical Faculty held a special meeting on the 4th instant, to take action on the death of Dr. Gerard E. Morgan, who died very suddenly from heart-disease, on Nov. 30. He was a fine physician, and for many years an active member of the American Medical Association.

Yours, etc.,

MEDICUS.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—Will you allow me a few lines in your valuable journal, in order to say how interested I have been in a communication by my friend J. G. Richardson, M.D., "Microscopist to the Pennsylvania Hospital," entitled "Notes on the Performance of Two One-fiftieth Objectives"?

Moreover, you will see that I have been complimented therein; and, as I never could bear *such* honors otherwise than gratefully, I beg just a word in friendly reply.

If my memory is not at fault, we have heard before of the peculiar properties of these lenses, especially of "my one-fiftieth dry, made by Powell and Leland," and of "my one-twenty-fifth immersion, made by Wales," and I think these historic objectives enabled their owner, by "long study and constant practice," to detect a skin on the blood-corpuscles, brief accounts of which optical triumph have come to us in the journals of this and other countries, and also in the proceedings of societies which indulge occasionally in the dissemination of useless knowledge.

I was naturally, perhaps justifiably, interested, then, when these two superior lenses, and another doubtless as good, were "tested" by an expert, and the result published for our information.

It is to be regretted that Dr. R. did not define more clearly the special optical and mechanical peculiarities of these lenses, for they are nationally dissimilar, and when he writes of their special performance he leaves the impression that inexcusable defects exist either in the lenses or in the manipulator.

Let us see. "The pleurosigma angulatum offered no difficulties;" of course not, with a one-fiftieth. Yet was it resolved, or were only lines seen? A good four-tenth resolves it into *dots* by central light easily.

Surirella gemma, recommended by Hartnack as a test for high powers, measures, on an average, one-two-hundred-and-fortieth of an inch, longer diameter. The transverse lines are seventy-two in the one-thousandth of an inch; the longitudinal, eighty-four to the one-thousandth. The "basket-like arrangement of these lines, produced, according to Hartnack, by elongated hexagonal areolations," and which Dr. R. says "came distinctly into view in a noteworthy way," is a misinterpretation of structure, as proven long ago by Dr. Woodward and Mr. Moorehouse, who, with others, resolve them into dots, and under lower powers than the one-fiftieth. The separation of lines or dots only eighty-four thousand to the inch is not the limit of best modern lenses, but they do lie on the border-line of unpractised illumination, and hence Dr. R. did not accomplish resolution in Surirella.

When these lenses were turned on the Amphipleura pellucida, only the "markings near the edges of the frustules" were seen, and the Boston one-fiftieth did the best work. In well-defined words, the test was not resolved at all, only seen, like most microscopical work. In the hands of Prof. J. Edward Smith, a Tolles dry—and *very* dry—one-eighth resolved the amphipleura into beads; and, with lowest eye-piece, both sets of striations were easily seen. (See *Mon. Mic. Jour.*, September, 1873.)

We are told next how the Podura scale (what species?) looks under high power, by *central* light. On some good specimens of the doctor's own mounting, we are informed that "the definition of the exclamation-marks is somewhat superior" under the Boston lens to that under "the one-fiftieth made by Powell and Leland, and the immersion one-twenty-fifth made by Wales." How much superior? What was the character of this definition by *central* light?

Here the histologist is interested, and naturally wants to learn whether these high-power lenses will help him in his honest work. If this central-light definition was so *inexpressibly* bad, what were the aberrations?—negative, or positive? How shall we judge from the accounts? Which is it don't define?—the lens or the—oh, I *won't* think it! However, in optical fogs like these, discoveries have been made. Neither bears the C eye-piece "without marked loss of definition."

We have bad definition, again, on the salivary corpuscles,—at least we infer from the account that the molecules were nebulously revealed by all the lenses. The salivary corpuscle is an easy test for definition, a good one-fifth showing every morphological element with vivid distinctness.

These high powers, however, reach their climax on the Bacterium. These organizations were "limited by a delicate hair-line, almost as fine as can be drawn by an ordinary writing-pen." This is better work, and a clearer report. Is it not strange that the same lenses

which cannot define the test podura or molecules in salivary corpuscles should come up to hair-lines in Bacteria? There may have been some special force operative here, which only the initiated can understand.

"In order to overcome the insuperable obstacle which has hitherto prevented a one-fiftieth being tested in Philadelphia, I have devised the following method, etc.,"—covering the object with thin mica. This is too fast. In the aboriginal days of microscopical technology, mica was used in lieu of glass (and it is still employed by some who are content with approximations), but was abandoned. It is not homogeneous, like good glass, and is so easily scratched that misinterpretations were unavoidable by inexperienced observers. If those Bacteria were seen through mica, I can understand the hair-lines, and "cylindrical lenses," and all the rest. Moreover, the old plan as now revived as original is exceedingly clumsy, and presents the insuperable impediment of two thicknesses of glass beneath the object, which would interfere with *best* illumination. The step is retrograde, and, compared with slides covered with thin glass by Möller,—thin enough for the one-fiftieth,—and which have been in our hands for several years, would be useless.

Finally, Dr. R. acknowledges these high powers are "not quite achromatic." Opticians do not seek to remove *all* color from their high combinations; they think best definition is secured by deficient compensation in the flint-glass systems; some allow the flint to preponderate. But Dr. R. does not tell us where this color appears,—within or without the focus,—nor what region of the spectrum is robbed to complete the picture.

My only object in writing is to bear my insignificant testimony against such testing of lenses, and to discountenance general microscopical platitudes, because they enfold beginners with chromatic haze, conveying the unmeant impression that the truth has been uttered, whereas only fragments and torn patches of the garment of the immortal goddess have been held up to view.

J. G. H.

PROCEEDINGS OF SOCIETIES.

MEDICAL SOCIETY OF THE COUNTY OF ALBANY, NEW YORK.

SEMI-MONTHLY MEETING, NOV. 25, 1874.

DR. JAMES S. BAILEY, PRESIDENT, in the chair.

EPULIS OF THE LOWER JAW.

DR. LEWIS BALCH reported the following case: Thomas Burns, æt. 8, American, admitted at St. Peter's Hospital, October, 1874 (service of Dr. Balch). The mother says that almost a year ago she noticed that one of the teeth on the right side (the canine) had grown inside of its fellow to the left. The incisor was extracted, and a "lump of flesh" grew in its place. This did not increase in size until almost five weeks before admission. At that time the canine was drawn by a doctor, who lanced the "lump." Nothing but blood followed the incision, and since that time the lump has grown quite rapidly. Patient, up to the present time, has enjoyed good health. Family

healthy. Patient has been in the habit of picking up cigar-stumps in the street and smoking them, and also of chewing tobacco. Examination shows a dark-colored fungous growth in the right side of the mouth, part in front and part behind the teeth, having its base in the lower jaw. It has pushed before it the incisor teeth, crowding them over the ones adjoining, rendering the teeth very irregular.

Dr. Balch removed the fungous growth, but, owing to the hemorrhage, it was decided not to remove the bone, which was largely implicated, but to allow the patient to recover from the present operation, and then proceed to remove the part necessary for complete extirpation of the growth. The hemorrhage was controlled by pressure with picked lint. Microscopic examination of the part removed showed it to be cancerous in character, characteristic cells being easily found.

October 30.—The patient, having recovered from the first operation, was etherized, and an incision three and a half inches long made along the under edge of the jaw, from a point about an inch and a quarter to the left of the median line, to the right facial artery, which was not severed. The flap thus made was turned up over the mouth, and the bony part of the tumor removed by bone-forceps. The incision was made in the manner stated, so that if the disease was found to extend through the whole depth of the jaw, excision could be performed. It was, however, found unnecessary to excise, hard bone being below the alveolar processes.

Two ligatures were applied, and the wound closed by three hare-lip pins, with intermediate sutures of fine silk. A packing of picked lint was applied on the inside.

November 2.—The pins were removed to-day. There is some swelling of the face, but the patient does not suffer any pain, and is in excellent condition.

November 4.—Four sutures were now taken out. The wound has healed by first intention, almost throughout. The ligatures came away to-day. Inside the mouth the wound looks healthy, with but little discharge. A lotion of nitric acid, 3i to Oj of water, is ordered as a wash.

November 13.—External wound is entirely healed. Some few pouting granulations are seen springing from the right side of the internal wound, and look suspicious. At the suggestion of Dr. Swinburne, they are touched with chloride of zinc. Patient is around the ward.

November 16.—The exuberant granulations are touched with chloride of zinc. Patient doing well, and wound granulating healthily.

November 18.—Granulations have subsided, and the wound is rapidly healing.

November 23.—Patient nearly well, and left the hospital without telling his intentions.

DR. THOMAS BECKETT said that from the drawing he recognized the case as having been seen by him in the latter part of last summer. When he saw it there was a tumor of some size, and it had lifted the teeth upward; they were lying, as it were, in the top of the tumor.

DR. G. H. BENJAMIN said that he had treated a similar case, which was supposed to have arisen from an ulcerated tooth. In lancing it, nothing but blood flowed. A year afterwards, the tumor was developed into a considerable mass on the outer side of the gum.

OPERATION FOR FEMORAL HERNIA.

DR. O. H. E. CLARK reported the following: Mrs. H., about ten years ago, in lifting a wash-tub, became ruptured, about ten weeks after confinement. Two years later, a severe attack ensued, on lifting a heavy

vessel of water. After some difficulty, the intestine was returned, but no preventive treatment followed. Dr. Clark was summoned in haste in the night, January, 1873. He found a double femoral hernia existing. The left side was of the size of a hen's egg, tense and painful to the touch, and appeared as if an enteroepiplocele.

There was intense pain in the abdomen; pulse 122, weak and small; countenance ghastly, and covered with a clammy perspiration. The voice was weak, and the patient completely prostrated, and seemingly near death. Taxis having failed, gr. $\frac{1}{2}$ of morphia was administered, and a large warm linseed poultice, sprinkled with tincture of opium, was applied. This composed the patient, and she slept for an hour or more, when she felt relieved. Taxis was again repeated, and the hernia was returned. The first intimation of the return was a peculiar sensation and gurgle of flatus in the abdomen. The plan operating as successful was that recommended by Malgaigne.

March 20, 1874, Dr. Clark was again summoned. The patient had passed her sixtieth birthday; was very thin, with bad appetite, and suffering from some urinary derangement.

The left hernia was now strangulated, and was large and hard. Vomiting and pain were present. Patient had resorted to her usual method of reduction, and had failed. She was less weakened than at Dr. C.'s first visit. The tumor was about the size of a large goose-egg, and occupied the space intermediate between Poupart's ligament and the perpendicular. When pressed, it gave a sensation like that of a large sausage coiled on itself in a sac under the integuments. It was dull on percussion, and hard to the touch, excepting on that portion near to the ring, where it was resonant on percussion and soft to the touch. The use of morphia and of the poultice, with attempts at taxis, were made a number of times in the next few days. But, all attempts having proved abortive, anæsthesia was produced with chloroform, the effect being maintained with ether. Dr. Featherstonaugh kept her under its influence for more than three hours. Taxis was attempted by all present, and, having failed, a transverse incision of about two inches, and another perpendicular to the first, of three inches, completely exposed the tumor, covered by layers of fascia devoid of adipose tissue.

The doctor departed from the usual manner of procedure, and, instead of dividing the different layers on the director with a scalpel, he made use of a pair of small, sharp scissors, with one of the blades made blunt at its extremity, which, although small, is somewhat square. It was from a case of instruments made for operating on the eye. With these scissors he carefully divided the tissues down to the sac. Dr. Clark was of the opinion that the scissors operated with more precision than the director and scalpel; they enabled him to divide the fascia much more minutely than could have been done with the director passed between the layers and cut down to with a scalpel; and in opening the hernial sac their superiority was manifest. Long directions are given in text-books how to hold the scalpel flatwise, so as not by any mischance to cut the bowel. With the scissors no such accident can occur; and, while they do not exclude the director, on which they may be guided, they may to a certain extent be used without it. The small, blunt, square point will divide layers with much greater minuteness than the director, and without the danger of the sharp cutting point of the scalpel. Before the director can be passed under a layer of fascia, it must be incised with the scalpel, and while doing so with a sharp-pointed instrument an accident might possibly occur. When the sac has to be opened, it can be pouched up and nipped with more precision than can be attained with the scalpel, which is always

liable to slip in a little farther than was intended. Again, when the director has been introduced and run along the internal surface of the anterior wall of the sac, if a knife is used from the outside to cut down to the director, or is run along the groove, or if the wall of the sac is lifted from within on the edge of the knife, possibly a piece of the intestine might be opened which has doubled over the director; but if the blunt blade of the scissors is run in the groove of the director, and kept well pressed against the wall of the sac, it can actually be seen, and the operator may feel certain that nothing intervenes between it and the sac in cutting that structure.

The hernial sac was whitish-yellow, thick and tough, and appeared united to the fascia by minute blood-vessels. After having become satisfied that this was truly the sac, the operator requested the assistant to push the contained viscus upward towards the abdomen; he then pinched up a minute fold of the sac and proceeded to open it as described. Serum ran out in large quantities. After the sac was empty and the hernia was returned into the abdomen, the patient was placed in a position favorable to its exit.

An examination of the protruded part showed it to be omentum. From the symptoms and sensation of returning flatus, there was no doubt that some of the intestine was originally extruded, and was returned by taxis. The omental mass was about three inches long by two wide and one and a half thick; it was very pale, and firmly embraced by the falciform border of the fascia lata. All attempts to return it failed.

Hey's ligament, as well as the deeper Gimbernat's ligament, having been divided in the usual manner, then carefully the whole was carried with the finger a little to the right, into the cavity of the abdomen. Even with the free incisions used, considerable difficulty was experienced in returning the mass, from its size, and, at the end of the process, from firm and evidently old adhesions, two of which were severed near the sac, and, as they bled freely, light ligatures of fine silk dipped in carbolic acid solution were tied around them, and, after their ligated and strangulated tips had been touched by the same strong solution, they were introduced into the abdomen.

The second mass, being of considerable size, caused more anxiety,—fearing decomposition and consequent peritonitis, besides the possibility of pyæmia; but it was held that to return it into the abdomen, after a thorough application of carbolic acid solution, was the best thing practicable.

The pulse being weak, the parts were brought together and closed with carbolized sutures, leaving about one-quarter of the perpendicular incision open below, to favor drainage. A few straps of adhesive plaster were put over the superior part of the wound, over which a pledget of lint soaked in carbolic acid was lightly placed, and as lightly retained *in situ* by a bandage.

After reaction, the patient was removed to a bed the feet of which were raised four inches on blocks of wood. A small pillow was put under the thigh. Pulse 110. Ordered morphia, gr. $\frac{1}{4}$, absolute quiet, and a small piece of ice occasionally. She slept soundly during the night, awakening the next morning heavy, stupid, and feverish; pulse 120, and rather irregular; temperature 103°. Some pain in the abdomen, but she was so oppressed that no connected answers were obtained. Applications of hot carbolized water were made over the abdomen, extending over the inguinal region and thigh, and covering the wound.

These applications were changed every half-hour for the next two days. Diet—beef-tea, milk, and arrow-root, in very small quantities, often repeated. Ordered potassii acetat and potassii nitrat, there being a history of urinary troubles.

Second day, 9 A.M.—Pulse 104, extremely weak and irregular; temperature 102.7°; respiration 32; tongue dry. Wound has united by first intention, in the upper or horizontal incision, but the perpendicular cut has not. Its edges are pale, and pus commences to ooze out.

Third day, 10 A.M.—Wound sloughing in all directions, especially invading the abdominal integuments; one and a half inches above Poupart's ligament, slough is very deep. Excised dead tissue freely; took out all sutures and applied charcoal poultices, made with carbolic acid lotion.

Besides beef-tea and milk, ordered 1 gr. quinine, 2½ grs. sulph. soda, and one teaspoonful of brandy, every three hours. Passed one pint of urine in twenty-four hours. 9 P.M., sloughing extended still farther on abdomen. Is very weak; ordered quinine, gr. i every hour, and morphia, gr. ¼ every evening.

Fourth day.—Had a good night's rest; passed a more comfortable day, disturbed, however, by colicky pains. Wound surrounded by a broad, red, erysipelatous border. The edges keep crumbling down, but the bottom of the wound is granulating. Opened an abscess in the lower and deep part of wound. Had wound stuffed with lint cut very fine and steeped in carbolic acid lotion, and packed tight charcoal poultices over the whole. Dressings to be changed every three hours.

Fifth day.—Improving. Pulse 80; temperature 90°; urinates freely; wound looks better. Granulations very flabby. Touched it freely with nitrate of silver, then had it packed with lint soaked in Edinburgh red wash, made with carbolic acid lotion, thus:

Zinci sulph., gr. xvi;
Spt. rosmar., gtt. ii;
Spt. lavand. comp. ad ʒviii.

6 P.M.—While sleeping, felt faint. Awoke cold, dizzy, unable to see out of left eye; limbs numb. Gave brandy, and she revived. In the evening, flushed and feverish. A red and painful spot forming on the left shoulder.

Sixth day.—An abscess formed on the left shoulder, just below the angle of the left scapula; gives great annoyance. Feverish and restless.

Seventh day.—Patient feels worse. A large sinus exists in lower part of wound. Passed in the director and cut down to it from without, and inserted a tape seton. Opened abscess in back, out of which ran very fetid matter. Patient looks weak, yellow, and sunken. Ordered beef-juice and eggs, besides previous treatment. Touched the wound with nitrate of silver, and then packed it with lint dipped in carbolic acid lotion.

Gave starch-water injections to move the bowels.

Eighth day.—Much better; pulse 100. Wound granulating. Approximated edges with adhesive plaster.

Ninth day.—Has vomited, probably from disagreement of food. Had a liquid stool. Wound granulating. Omitted packing; strapped it lightly.

Tenth day.—Improving.

Thirteenth day.—Recovering rapidly.

Sixteenth day.—Wound almost healed; thoroughly convalescent, and in three months the hernia appeared radically cured; but it has since occurred again, and obtained considerable size. In spite of her experience, she will not wear a truss.

The points of special interest are as follows:

1. The reduction of the enterocele under the influence of an anæsthetic, leaving the epiplocele behind. From the symptoms, the peculiar feeling of returning flatus, and subsequent diminution in the bulk of the tumor, there is no doubt of the correctness of this view. After this sensation and sound of returning flatus and of giving way had been distinctly experienced, there occurred what had not taken place before: the tumor became smaller on pressure and larger when suspended, showing

that a communication had been established with the interior of the abdomen; also, that the peculiar sensation and sound referred to as occurring in the early part of the taxis were not due to serum passing into the cavity of the abdomen, for such did not occur whenever that took place. The strangulated piece of bowel need not have been large. In Gross's Surgery there is mentioned a case where the protruded intestine was not larger than a peanut deprived of its shell.

2. The size of the tumor. Femoral hernia is stated, as a rule, not to exceed an almond in size. This case shows an exception.

3. The large amount of serum. Only a few drachms are generally found in femoral hernia. In this case, at least eight drachms flowed away. The returning into the abdomen of the serum when the hernia was subjected to pressure, thereby considerably diminishing its bulk, and leading to delusive hopes of its reduction, is a peculiarity not mentioned by authors, and worthy of being remembered, as it might lead to an undue prolongation of the taxis, to the great injury of the patient.

4. The temporary radical cure of the hernia, following on the extensive sloughing that resulted from the manipulation and operation, and which might probably have become permanent had the patient been more governable and had she steadily worn a truss.

Dr. Clark asked how long the operation should be deferred. He believed the answer to the question was becoming more unanimous, that the moment the physician feels satisfied that taxis is not likely to succeed, and when the patient's symptoms progressively increase in severity, then, without waiting and subjecting the patient to dangerous manipulations, the operation should be performed.

The surgeon should always keep clear in his mind that but one cure exists,—the return of the intestine into the abdominal cavity,—and that every moment it is out is not simply a moment lost, but that increased danger is incurred. The circulation in the strangulated portion is at first impeded, and later altogether arrested, and the involved intestine is marching surely to gangrene, and the patient to death. In other diseases there may be a time of suspension, during which it may be prudent to avoid heroic measures; in them, time alone is not a source of danger; but here, unless reduction is made, the patient dies.

Another important point to keep in mind is, that reduction at any time will not save: it must be reduced while the intestine or omentum is yet in a fit state to live, and not to produce inflammation of the peritoneum when returned. He did not mean to condemn a scientific, persevering taxis, but the rough practice of continuing beyond the limit of safety, either as to the force used, the severity of the symptoms, or the valuable time consumed during which the patient might be saved were the operation performed.

Let us inquire, now, whether the operation, if performed in time, when the system and parts are in a condition in which recovery after any operation is expected,—whether the operation, thus performed, is fraught with the great danger which has so long made it a terror to the profession, or whether this estimation has not arisen from the operation being deferred until too late, and therefore followed by fatal results. It is believed by surgeons who have had most experience in operating under favorable circumstances, that the mortality of patients is materially diminished in such cases. Holmes's System of Surgery, the standard exponent of cotemporary British surgeons, says, "We believe that death resulting from strangulated bowels would be a rare occurrence if it were practicable to return every strangulated enterocele within twelve hours after the commencement of the symptoms, even assuming that the

cutting operation be required to accomplish that end in every case." Sir James Paget, in his lectures on strangulated hernia, strongly urges his auditors to operate in all cases of hernia which have become totally irreducible, if vomiting continues at intervals, even if no other symptom seems to call for active interference; and he adduces numerous cases to prove the propriety of the rule. On another occasion he says, "I have no doubt that for every case in which an operation has been avoided by waiting, there have been two cases in which lives have been lost by waiting too long."

Sir James Paget has operated about one hundred times for strangulated hernia, and has had a large experience in this surgical lesion.

J. Cooper Foster, Surgeon to Guy's Hospital, says, "Make, then, one decided attempt, under chloroform, and, if you fail, operate. You cannot hear this too often, because forcible taxis and delay in operating are the great causes of death of all cases in our hospital. If I myself had a rupture, no one should try to reduce it except the operator, with the proviso that if he failed after a very moderate attempt, he should at once proceed with the knife."

T. Legros Clarke, Surgeon to St. Thomas's Hospital, holds "that the fatality of our cases is chiefly due to delay and the repetition of unsuccessful attempts at reduction by taxis. I am satisfied," says he, "that the risk attending an operation for strangulated hernia is very much aggravated. If gentleness and forbearance were more generally adopted in applying the preliminary measures undertaken to afford relief, and purgatives and procrastination (often self-inflicted) were eliminated from the treatment, I believe that the statistics of the operation for strangulated hernia would present a far more favorable aspect than is at present the case."

Dr. Frederick Hyde, in an article on hernia and its complications, published in the Transactions of the Medical Society of the State of New York for 1867, warmly advocates early operation, even, in many instances, after only fair trial of the taxis, in which advantage of all adjuvant means has been taken. The writer terminates his treatise thus: "It is objected, to an early division of the structure, that it is too spoliative a measure, and is in conflict with the doctrines of conservative surgery. We submit whether it does not savor altogether more of a justifiable conservatism to carefully divide the ligating tissue and relieve the already injured structure, than to repeat the trial to reduce them while we have the remaining unyielding structure." He is confident "that he has never seen a patient die on whom this operation has been made, from its own legitimate results, and his recollection assures him equally well that the fatality has been from the injury sustained by the parts before the incisions were made."

In these days of daring surgery, when the peritoneum—that cavity hermetically sealed to art by the fears of old surgeons—is boldly incised into for inches to withdraw therefrom an enormous cyst, fearlessly cutting away adhesions,—in these days, he says, herniotomy has lost its terrors, and surgeons at present generally agree that the fatal risk is not incurred in performing this operation, but in doing so too late. When a man is moribund, or surely going that way, operations are superfluous; and, blinded by delusive hopes of at length succeeding with taxis or other means employed, the surgeon too often allows his hapless patient to slip into that state in which all assistance is in vain.

Dr. MARCH spoke in praise of the paper read by Dr. Clark, and referred to the rarity of double femoral hernia. He was of the opinion that the dividing of the tissue with blunt scissors was a decided improvement.

He did not favor the idea of employing taxis long, but believed in operating early.

Dr. HANNON and others gave their views, which were essentially the same as those already expressed.

GLEANINGS FROM OUR EXCHANGES.

A REMARKABLE CASE OF PHLEBITIS (*Archives of Ophthalmology and Otology*, vol. iv. No. 1).—R. Wreden reports the case of a boy, æt. 15, who suffered from a terrible inflammation of the cerebral sinuses, caused by an acute inflammation of the middle ear, which had the characteristics of an otitis of the temporal bone.

After a slight improvement, the patient caught cold, and the inflammation of the sinuses returned with increased violence; high fever, with frequently recurrent rigors, continual nausea, with very frequent vomiting, giddiness, tinnitus, great weakness, apathy, somnolence, delirium, epileptiform convulsions, etc. The differences in these symptoms are all explained by the rapid spread of the inflammation of the sinuses from the right transverse sinus to the others.

Phlebitis of the internal jugular vein made itself known by enormous painful swelling of the corresponding side of the neck, without redness of the skin. The face was puffy and œdematous. There were clonic and tonic spasms of the sterno-cleido muscles, from irritation of the spinal accessory nerve in the jugular foramen. The phlebitis of the superior longitudinal sinus was marked by two symptoms of importance: repeated violent epistaxis, and epileptiform convulsions. These were due to the excessive choking of the blood-current from the surface of the brain. The affection of the right sinus cavernosus was manifested by phenomena of irritation and paralysis of the abductor nerve, the first branch of the fifth, and the oculomotor, and by phenomena indicative of blocking of the circulation in the eye.

The affection of the abducens, which came close to the outer wall of the cerebral carotid artery in the cavernous sinus, was indicated by internal strabismus of the right eye,—i.e., paresis of the external rectus. Pressure on the first branch of the trifacial caused unilateral headache, photophobia, etc.; pressure on the oculomotor caused ptosis. The symptoms of ischæmia of the eye were strongly marked, and consisted of œdematous swelling of the eyelids, of the conjunctiva of the eyeball, and the retro-bulbar connective tissue (exophthalmos).

The patient made a good recovery, the treatment having consisted of leeches, poultices, laxatives, and the administration of proper nourishment.

PROBABLE LEAD-POISONING FROM A BULLET LODGED IN THE KNEE-JOINT (*The Boston Medical and Surgical Journal*, November, 1874).—At a recent meeting of the Boston Society for Medical Improvement, Dr. Ellis reported the case of a man who had severe attacks of colicky pain in the abdomen, always preceded by obstinate constipation, and accompanied by vomiting. He subsequently had epileptic convulsions, became violently delirious, and died. About six weeks before his death, a blue line was noticed on his gums.

As it was known that twelve years previous the patient had been wounded in the knee, search was made, and a large conical leaden bullet was found imbedded in the inner condyle of the femur, its base being exactly level with the articular cartilage, its longest diameter parallel with the shaft of the bone between the two condyles. There was, therefore, a surface of

lead exposed to attrition, in a synovial cavity, where there was a constant secretion and absorption of fluid, and it would seem that there might have been absorption of some soluble salt of the metal.

PURPURA HÆMORRHAGICA (*The Lancet*, November 14, 1874).—Dr. W. B. Richardson divides purpura hæmorrhagica into three classes, distinct in their etiology, diagnosis, and treatment; the *aqueous*, in which the water of the blood is in excess, and the colloids relatively decreased; the *saline*, where some saline substance holds the colloidal fibrin in undue solution; and the *vascular*, where there is a degenerative change in the capillaries, and rupture or transudation is facilitated. Dr. Richardson believes that the character of the eruption varies in these several forms.

NOTES AND QUERIES.

THE NEW SCRIPTURES,

According to Tyndall, Huxley, Spencer, and Darwin.

(Genesis, Chapter II.)

1. PRIMARILY the Unknowable moved upon cosmos and evolved protoplasm.
2. And protoplasm was inorganic and undifferentiated, containing all things in potential energy; and a spirit of evolution moved upon the fluid mass.
3. And the Unknowable said, Let atoms attract; and their contact begat light, heat, and electricity.
4. And the Unconditioned differentiated the atoms, each after its kind; and their combinations begat rock, air, and water.
5. And there went out a spirit of evolution from the Unconditioned, and, working in protoplasm by accretion and absorption, produced the organic cell.
6. And cell, by nutrition, evolved primordial germ, and germ developed protogene, and protogene begat eozoon, and eozoon begat monad, and monad begat animalcule.
7. And animalcule begat ephemera, then began creeping things to multiply on the face of the earth.
8. And earthy atom in vegetable protoplasm begat the molecule, and thence came all grass and every herb in the earth.
9. And animalcula in the water evolved fins, tails, claws, and scales; and in the air, wings and beaks; and on the land they sprouted such organs as were necessary as played upon by the environment.
10. And by accretion and absorption came the radiata and mollusca, and mollusca begat articulata, and articulata begat vertebrata.
11. Now these are the generations of the higher vertebrata, in the cosmic period that the Unknowable evolved the bipedal mammalia,
12. And every man of the earth, while he was yet a monkey, and the horse, while he was a hipparion, and the hipparion, before he was an oreodon.
13. Out of the ascidian came the amphibian and begat the pentadactyle, and the pentadactyle by inheritance and selection produced the hylobate, from which are the simiadæ in all their tribes.
14. And out of the simiadæ the lemur prevailed above his fellows and produced the platyrrhine monkey.
15. And the platyrrhine begat the catarrhine, and the catarrhine monkey begat the anthropoid ape, and the ape begat the longimanous ourang, and the ourang begat the chimpanzee, and the chimpanzee evolved the what-is-it.
16. And the what-is-it went into the land of Nod and took him a wife of the longimanous gibbons.
17. And in process of the cosmic period were born unto them and their children the anthropomorphic primordial types.
18. The homunculus, the prognathus, the troglodyte, the autochthon, the terragen—these are the generations of primeval man.
19. And primeval man was naked and not ashamed, but lived in quadrumanous innocence, and struggled mightily to harmonize with the environment.
20. And by inheritance and natural selection did he progress from the stable and homogeneous to the complex and heterogeneous; for the weakest died, and the strongest grew and multiplied.
21. And man grew a thumb, for that he had need of it, and developed capacities for prey.
22. For, behold, the swiftest men caught the most animals, and the

swiftest animals got away from the most men; wherefore the slow animals were eaten, and the slow men starved to death.

23. And as types were differentiated, the weaker types continually disappeared.

24. And the earth was filled with violence; for man strove with man, and tribe with tribe, whereby they killed off the weak and foolish, and secured the survival of the fittest.—*Cincinnati Commercial*.

IMPROPRIETY IN AWARDING THE CERTIFICATE OF THE PHILADELPHIA HOSPITAL (BLOCKLEY).

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—I am credibly informed that to the students of the dental colleges of this city who attend the bi-weekly clinics of the Philadelphia Hospital (Blockley) is awarded the formal diploma or certificate of the institution, equally with the graduates of the regular medical colleges. Of the impropriety of this course there can be no doubt. As a certificate of attendance on clinical lectures at a general hospital, bestowed on medical graduates, little as such a document may really mean or be deserved, I do not now question its propriety. The certificate simply implies that the graduate, in addition to his ordinary collegiate course, has had at least some clinical opportunity at a general hospital. With regard to dental students, it may speciously imply a knowledge of the general subjects of clinical teaching, which, with their special and limited didactic course at the dental colleges, they cannot properly possess.

That the certificate of the Philadelphia Hospital, when thus loosely broadcast, is liable to abuse in being used as a guarantee of knowledge fitting its possessor, who is not a medical graduate, for the practice of medicine and surgery, is evident.

The clinics of general hospitals have but little bearing on dentistry, and there was never a general attendance of dental students at hospital clinics until the showy prize of the hospital certificate was promised to them at the Philadelphia Hospital. Now the dental students, in view of the expected pretentious document, attend that hospital in a body, with the distinct object, as several of them have asserted to me, of obtaining a certificate which no other hospital will give them.

If the rule of granting certificates of general hospitals to no others than medical graduates, and only on presenting evidence of such graduation, is to be departed from, a dangerous precedent of transgression will be established.

In another view of the matter, a hospital certificate that has become attainable without medical graduation will soon sadly depreciate in value.

The provincial doctor who adorns his office with the certificate of the Philadelphia Hospital will, on discovering a similar document emblazoned on the front door of the village tooth-drawer, be inclined to hang his depreciated testimonial out of sight.

I would not have the clinical opportunities of the dental student in any manner restricted, but he should not be awarded a credential that ought to be attainable only after medical graduation. To use the language of a good dental as well as medical authority, Dr. Garretson, in his recent article in your journal, "A specialist should not be received into the common brotherhood of medicine without his coming to a common platform as regards all that makes the doctor."

I am quite sure that the ethical bodies of our profession will agree with me that hospital certificates should be absolutely restricted to graduates of regular medical colleges, and that a contrary course must render the medical board of a hospital amenable to indictment of censorship.

VINDEX.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM DECEMBER 15 TO DECEMBER 21, 1874, INCLUSIVE.

COOPER, GEO. E., SURGEON.—Relieved from duty at Benicia Barracks, California, and assigned to duty at Point San José, California. S. O. 124, Department of California, Dec. 11, 1874.

BENTLEY, E., ASSISTANT-SURGEON.—When relieved by Surgeon Cooper, to report to the Medical Director at these Headquarters for duty. S. O. 124, c. s., Department of California.

WHITE, R. H., ASSISTANT-SURGEON.—Granted leave of absence for one month. S. O. 208, Department of the Gulf, Dec. 16, 1874.

PAULDING, H. O., ASSISTANT-SURGEON.—Assigned to temporary duty at Fort Snelling, Minnesota. S. O. 275, Department of Dakota, Dec. 14, 1874.

SEMIG, B. G., ASSISTANT-SURGEON.—Assigned to duty at Camp Halleck, Nevada. S. O. 124, c. s., Department of California.

DE LOFFRE, A. A., ASSISTANT-SURGEON.—To report in person for duty to Colonel N. A. Miles, 5th Infantry, commanding Indian Territory Expedition. S. O. 205, Department of the Missouri, Dec. 10, 1874.

SATURDAY, JANUARY 2, 1875.

ORIGINAL LECTURES.

ON THE PRINCIPLES WHICH GOVERN THE USE OF ELECTRICITY IN PARALYSIS.

An Abstract of a Course of Three Lectures delivered at the University Hospital

BY H. C. WOOD, JR., M.D.

LECTURE I.

GENTLEMEN,—In opening this winter's course I shall lay aside for a little while purely clinical teaching, in order to give you some instruction upon the principles that underlie the right use of electricity in paralysis; confining my remarks to this especial therapeutic employment of the force, because, beyond this point, medical electro-therapeutics is at present a perfect chaos, a mass of apparently contradictory facts out of which no spirit of man can bring any order until we have better, clearer ideas of the various diseases in which electricity is employed, as well as of the physiological action of galvanism. For a knowledge of these diverse facts you must trust rather to clinical experience than to scientific didactic teaching.

Let us to-day commence at the very bottom of the matter.

Electricity is a force which is developed in various ways, but which is essentially the same entity under all circumstances. When it is obtained by rubbing two surfaces together, it is known as frictional electricity; when by the union of two dissimilar metals, it is called galvanism. Frictional electricity is almost never used in medical practice, and I shall here say nothing more about it.

There are a large number of different patterns or arrangements of the elements which generate galvanism, but the ideal or typical cell may be said to be formed of two dissimilar metals immersed in some corrosive liquid, and connected with each other by a piece of wire externally. Under these circumstances the current starts from the metal most easily corroded, passing through the liquid to that less easily acted upon, and from this over the external wire to the starting-point. The external end

of the least-easily corroded plate is therefore always giving off electricity, and is known as the + or positive pole, whilst the corresponding end of the other plate is constantly receiving electricity, and is spoken of as the — or negative pole. When wires are attached to these plates they become, as it were, prolongations of the plates, and their ends constitute the poles. Thus, in the diagram, C = copper, Z = zinc, P and N = poles, and the arrows show the direction of the current.

As the electric current does not primarily exist, it is evident that in the typical or ideal galvanic cell there must be something which sets it in motion. This force is the so-called electro-motor force, and has been determined by physicists to be a definite quantity for the same combination of metals at the one temperature. This force is generated at the point of contact of the metals, and is in consequence of the law discovered by Volta, that when two metals are in contact with each other, a disturbance of the electrical conditions of those metals occurs. The amount and energy of this disturbance vary according to the nature of the metals, and experiments have shown that all metals have definite electro-motor powers or properties, and that they can readily be arranged in a regular series. A study of this series would, however, lead us far astray from the present point. The point which is to be especially borne in mind is the constancy of the electro-motor force, so that in any given combination of metals in a galvanic cell the electro-motor force is always the same, whether the plates of the metal be large or small, whether the solution be an acid, a saline, or pure water. The strength of the current is not, however, decided entirely by the electro-motor force of the cell. Every known substance refuses more or less imperiously to allow the passage of electricity. The best conductors oppose a really very great resistance. Now, it is evident this resistance is opposed to the electro-motor force, and that if it be greater than the latter it will altogether prevent the passage of any current. The strength of the current, then, depends upon the relation between the resistance and the electro-motor force; and we have the celebrated law of Ohm, which may be expressed by the formula

$$C \text{ (current strength)} = \frac{E \text{ (electro-motor force)}}{R \text{ (resistance)}}. \text{ This}$$

law experiment has shown to be imperative: no increase or diminution of the size of the plates, no change in the character of the solution, affects it.

The resistance to the current in a galvanic combination is a double one: inside of the cell the fluid between the plates opposes the passage of the electricity, and outside of the cell the conductor which completes the circuit also offers a resistance. The reason a battery almost ceases to yield a current when water is substituted for the acid usually employed is not a purely chemical one, but simply because water is an almost complete non-conductor, and offers triumphant resistance to the current, whilst the acid conducts and readily allows the current to pass. The entire resistance (R) is then

made up of two factors: the internal resistance (IR), and the external resistance (ER). The formula of Ohm may therefore be read $C = \frac{E}{IR + ER}$.

As already stated, where the plates of a cell are increased in size the electro-motor force is not increased, but as the surfaces of the plates are increased the diameter of the conductor—*i.e.*, the mass of fluids between the plates—is increased; and consequently, as the resistance in a conductor is inversely as the size of its cross-section, the strength of the current is increased. To make this a little clearer, suppose IR in a certain cell equal 10, then

$C = \frac{E}{10 + ER}$; if now the plates of the cell be

doubled in size, $C = \frac{E}{\frac{10}{2} + ER} = \frac{E}{5 + ER}$. A sim-

ilar result—*i.e.*, lessening of the internal resistance—can be achieved by shortening the distance between plates in the cell,—*i.e.*, the length of the conductor,—or by in any way making the intervening liquid a better conductor.

The change in the strength of a current by the increase of the size of the plates of the cells can readily be expressed by the formula of Ohm. If the letters signify as before, and the internal resistance be diminished y times by increasing the

size of the plate y times, instead of $C = \frac{E}{IR + ER}$,

C will be $\frac{E}{\frac{IR}{y} + ER}$.

If, instead of a single cell, a number of cells are arranged in such a way that the copper of one is connected with the zinc of the next, the electro-motor force of the combination is equal to the sum of the electro-motor forces of the cell; thus, if E = electro-motor force of the single cell, and y = the number of cells, the electro-motor force of the battery will be yE . It is also plain that the internal resistance of the battery is also increased y times, so

that the formula of Ohm will stand $C = \frac{yE}{yIR + ER}$.

Of course, the strength of a current is greatly affected by the external resistance. In very many instances the external resistance is very great. Suppose, then, this external resistance in a given case be 1000 times the internal resistance, the formula of

Ohm will read, $C = \frac{E}{IR + 1000 IR}$. It is evident

that under these circumstances IR, the internal resistance, becomes very insignificant, and that very little is gained by increasing the size of the plate,—*i.e.*, by diminishing the internal resistance; for if the plates were increased fivefold, the increase of the current strength would only be the difference

between $\frac{E}{5IR + 1000 IR}$ and $\frac{E}{IR + 1000 IR}$, a difference which is very slight. On the other hand, when the external resistance is very great, every-

thing is gained by increasing the number of cells,—*i.e.*, increasing the electro-motor power; for

$\frac{5E}{5IR + 1000 IR}$ gives a very different result from $\frac{E}{IR + 1000 IR}$. When, therefore, the external resist-

ance is many times greater than the internal, practically nothing is gained by increasing the size of the plates; everything by increasing the number of elements.

The converse of the above reasoning also holds. If the external resistance be very slight, the internal rises in importance. Thus, suppose $ER = \frac{IR}{1000}$.

Then the formula would be $C = \frac{E}{IR + \frac{IR}{1000}}$. In

this case a great deal is gained by increasing the size of the plates, for $\frac{E}{\frac{IR}{5} + \frac{IR}{1000}}$ gives a very dif-

ferent result from $\frac{E}{IR + \frac{IR}{1000}}$. In such a case, by

quintupling the size of the plates the strength of the current is practically increased fivefold. On the other hand, it is plain that when the external resistance is slight, the gain by increasing the number of cells is a slight one, for the internal resistance is increased as many times as the electro-motor force. Thus, if five cells are used, the

formula will be $C = \frac{5E}{5IR + \frac{IR}{1000}}$, which will, of

course, give practically the same result as $\frac{E}{IR + \frac{IR}{1000}}$.

The law may then be stated to be that when the external resistance is very slight, increasing the number of the elements has no practical effect upon the strength of the current, whilst an increase of the size of the elements has the greatest effect.

When there is no very great disproportion between the internal and the external resistance, it is evident that the strength of the current may be increased either by increasing the size or the number of the elements.

Thus, if $ER = IR$, $C = \frac{E}{IR + ER} = \frac{E}{IR + IR}$; and increasing the size of the plates fourfold will give the formula $C = \frac{E}{\frac{IR}{4} + IR}$; or increasing the number of

elements to four will yield the formula $C = \frac{4E}{4R + R}$.

Perhaps the result will be clearer if figures are used. Suppose $E = 100$, $IR = 10$, and $ER = 10$. Then the first formula will be $C = \frac{100}{10 + 10} = 5$; the

second, $C = \frac{100}{\frac{10}{4} + 10} = 8$; the third, $C = \frac{400}{40 + 10}$

$= 8$. When, therefore, the *external and internal resistance are equally balanced, the current strength is equally increased by increasing the number or the size of the plates*. The application of these principles to electro-therapeutics is a very simple one. In the ordinary applications of electricity to the body the resistance of the tissues is enormous—very many times greater than the internal resistance of any battery, and consequently the latter may be totally disregarded. Hence for ordinary purposes the formula

stands $C = \frac{E}{ER}$, and power can be gained only by

increasing E ,—that is, by augmenting the number of cells.

When, however, it is desired to act upon the blood in an aneurismal sac, the needles are brought close to each other; and, moreover, the blood is a comparatively good conductor of the electricity. Hence, in such cases, the external resistance is so much reduced that the internal becomes of such importance that it should not be overlooked. It follows, therefore, that when an aneurism is to be acted upon the plates should be increased in size, whilst at the same time a number of cells should be used.

In the so-called “galvano-cautery” the current is not passed through the body at all, but through a wire, which is thus kept at a white heat. In this case the external resistance is vastly less than when human tissues form a part of the circuit. Hence it becomes a matter of importance to reduce to as great a degree as possible the internal resistance, and the elements or plates should be very large and should be placed very close to one another in the cells. The external resistance is not, however, so slight that it can be entirely overlooked, and hence a number of cells are combined with one another, so as to give sufficient electro-motor force.

You will notice, gentlemen, that I have in my lecture entirely avoided such expressions as quantity and intensity. It would occupy too much space for me to dwell upon the fact that, to use the language of one of the most eminent of living writers, “these terms are remnants of an erroneous theory.” It is, however, of the greatest practical importance that they be banished from electro-therapeutics. The amount of mystification which has been produced by talk concerning the therapeutic effects of currents of large quantity with low intensity as contrasted with those of currents of high intensity and low quantity is equalled only by the amount of nonsense which has been written. Currents of galvanism have really only one attribute,—*i.e.*, current strength,—and that is in strict obedience with the law of Ohm.

Again, a dense fog has been thrown around the subject of electro-therapeutics by the idea that there are various essentially different forms of galvanism. As you know, the current which flows from a cell or a combination of cells is spoken of as a *continuous*

current, or sometimes as a *primary current*; besides this, modern therapeutists use another series of currents, which are known as the *induced currents*.

The term *primary current* is often applied to one of these induced currents. If we employ the name *continuous current* for that current derived from the galvanic cell, we must continually be speaking of the interrupted continuous current, which certainly is inelegant. I shall, therefore, employ the name *chemical current* or *galvanic current* to designate that form of galvanism which is generated in the galvanic cell.

If a coil of insulated wire have a bar of soft iron placed in its centre and be surrounded by an external coil of wire, when a chemical current is passed through the first coil, owing to physical laws which I shall not stop to consider, every time that the galvanic circuit is completed or interrupted a brief current of electricity is induced in the inner or first coil, and also a similar current in the outer or second coil. The only physical facts which it is necessary for us to know are that these induced currents are very brief and of great strength, also that they are to-and-fro currents,—that is, run in opposite directions in each individual coil. Thus, in the inner or first coil, when the galvanic circuit is closed the induced current in the inner coil runs parallel to the generator chemical current, but when this current is broken the induced runs in a contrary direction. In the outer coil the induced current, which is instantaneously developed when the galvanic current is sent through the inner coil, pursues an opposite direction to that of the chemical current; but when the latter is broken, the return induced current in the outer coil runs parallel to the generator current.

As these induced currents run backwards and forwards, to and fro, in this way, it would appear that there could not be any negative or positive pole to the battery which generates them, for if one end or pole of the wire constituting the coil be negative in regard to the first induced current, it must be positive in regard to the second or return current. This is, gentlemen, assuredly true so far as concerns the outer or second coil, but is not true for the inner or first coil, as you will readily understand by means of this diagram of an induction battery.

It is plain that when the current is passing, the hammer h being in the position represented in the diagram, m will become magnetic and attract h . This at once breaks the current, and an induced current runs through the first coil and is received by the patient grasping the handles $P P$. The instant the current is interrupted, m loses its magnetism and the spring-hammer flies back. Now the circuit is closed, and for the second time an induced current runs through the first coil c . It is evident, however, that this induced current of closure will not pass through the body of the person grasping the handles $P P$, but will pass along h through the cell to the other end of the coil, as a shorter route and one of vastly less resistance. It is plain that from the inner or first coil the induced current of broken circuit alone passes through the body of the patient.

In regard to the outer coil, it is evident that when

the circuit is closed the momentary induced current must run through the body of him who grasps the handles P' and P' , and that the return current which passes when the circuit is broken must take the same route.

G Galvanic element, with the + and — metals in it.
 c Coil in which the primary induced current or currents of the first coil are generated.
 h Spring-hammer or vibrator.
 m A piece of soft iron becoming a magnet when the current is passing.
 2c Outer coil in which secondary induced current, or current of the second coil, is generated.
 P Handles of inner coil.
 P' Handles of outer coil.

It follows from the above considerations that the *current of the first coil* runs through the patient *only in one direction*, and electricians may correctly mark poles + and —; but that the *current of the second coil* runs in *both directions*, so that any designation of its handles as positive and negative is incorrect. The only justification for the marking of the secondary or outer current poles, as is often done, is found in the fact that the induced current of the broken circuit is stronger than that of the closed circuit. Hence it is that with very strong currents you can sometimes distinguish between the two poles when grasped in the hand. The difference is, however, a slight one, and for all practical purposes the induced current of the outer coil is a to-and-fro one, without any negative or positive poles.

If a strong continuous galvanic current be passed through a person, a shock is felt at the moment of making and breaking the circuit, but whilst the current is passing no sensation is perceived except at the points of entrance and exit. Or if the current be passed through the nerve of a muscle, that muscle violently contracts at the moment the circuit is made or broken, but whilst the current is flowing the muscle is quiescent. If an induced or faradic current be passed through a nerve, the muscle supplied by that nerve is thrown into a violent continuous spasm. The reason of this is obvious. The

so-called faradic or induced current is, as has already been stated, a succession of instantaneous broken currents for the first coil, and as brief to-and-fro currents for the outer coil; so that the circuit is continually being closed and broken, and the muscle is continually excited to action. There is, therefore, a different result achieved in the application of the continuous and induced currents, not because there is any real difference in their nature, but because the mode of application is diverse.

Most electricians to-day teach that the true galvanic current is very different from the faradic current, and many, like Duchenne, persist in asserting that the currents of the first coil are essentially different from those of the second. Galvanism is, however, galvanism, its nature and attributes probably always the same; the faradic currents are lacking in the chemical power of the continuous current because they pass so quickly that they have not time to exert a chemical influence. You know gunpowder can be passed so quickly through the hottest flame as not to ignite. The secondary induced current differs somewhat in its action from the primary, simply because the latter is not a to-and-fro current, and we cannot readily convert an induced into a galvanic or chemical current, because we cannot readily tie together, as it were, the ends of the brief currents into one. I have myself little doubt that if we could get the interruptions at the rate of many thousand times a minute, we should find that the primary induced current would act as a continuous current.

We can readily, by mechanical means and contrivances, interrupt the continuous current, or even rapidly reverse the poles so as to give a to-and-fro current like that of the outer coil. When this is done, it is impossible to distinguish between the action of the galvanic and that of the faradic current in producing muscular contractions. It is true that in certain diseased states of the muscle it has been asserted, and with apparent reason, that the action of the induced current is essentially different from that of the true galvanic current. Nevertheless, when the matter is closely investigated, these abnormal muscles yield us the most cogent proofs of the identity of the two currents. The consideration of this must, however, be postponed until we are more advanced in our study. Our efforts at our next meeting must be to discover how or why it is that muscular contractions are caused at the making and breaking of circuits.

ORIGINAL COMMUNICATIONS.

HYPÆMIA FOLLOWING THE OPERATION OF DISCISSION.

BY ALBERT G. HEYL, M.D.,

Assistant-Surgeon to the Eye and Ear Institute.

HYPÆMIA, or a collection of blood in the anterior chamber of the eye, consequent upon the operation of discission when performed through the cornea, is one of those rare occurrences upon which we sometimes stumble in practice, but which,

though curious and unique, are also of great practical interest. The history of the case in which this condition occurred is as follows:

The patient, W. G., a healthy-looking German lad, aged 10 years, was brought to the Eye and Ear Institute June 22, 1874, for an opinion concerning his right eye. Two weeks previously his parents had noticed something wrong about the eye, their attention having been attracted by the white, glistening speck forming the background to the pupillary space, and due to the opaque lens. The previous history indicates that the boy has suffered more than is usual from the diseases of childhood, but apparently with little effect upon his general nutrition. There was no history of injury to the eye. The urine was normal.

On examination of the eyes, the following was noted:
Right eye.—Anterior chamber shallow, pupil moderately dilated. Lens presenting the ordinary appearance of soft cataract; a narrow band of less opaque lens-substance was noticed running across the lens for about two-thirds of the way, then bifurcating and continuing on to the equator of the lens, and marking the line of separation between its segments. Light perception and projection good.

Left eye.— $V = \frac{2}{3}\%$. Hypermetropia $\frac{3}{4}$ present. Oblique illumination and ophthalmoscope reveal nothing abnormal.

The boy was admitted into the Presbyterian Hospital, and on the 25th of last June the operation of discission was performed by Dr. Strawbridge, with whose permission this case is reported. The needle, as usual, was entered through the outer lower quadrant of the cornea, quite obliquely, however, owing to the very shallow anterior chamber and the capsule ruptured by a single tear. On withdrawal of the needle, we were greatly surprised to see the anterior chamber rapidly fill with blood. The usual after-treatment was observed; the blood was absorbed in about a day; no marked symptoms of irritation supervened. On examination, a few days afterwards, a synechia posterior directly downward was discovered.

The second discission was made July 12; the same phenomenon was observed; all the blood was absorbed in twenty-four hours, with the exception of a small thread-like clot lying in a chink of the partially absorbed lens, and resembling a minute blood-vessel; careful and repeated examination showed, however, that it was merely a clot-shred.

The third discission was made August 13. The hemorrhage again recurred; the blood was seen to ooze out of the iris-tissue at different points, then to coalesce until the anterior chamber was full.

October 20.—Lens seems to be completely absorbed; a large amount of capsule visible, appearing like an empty shell behind the iris and maintained in position by synechial attachments. A large hole exists in the centre of the anterior capsule. $V = \frac{2}{3}\%$, with convex 4. Ophthalmoscopic examination revealed some vitreous cloudiness, but nothing further, owing to the extreme restlessness of the patient. No opportunity for further examination has been afforded.

The main interest of this case hinges, of course, upon the occurrence of hypæmia evidently resulting from the operation; and the inquiry at once arises as to the source and cause of it.

1. As to its source. Undoubtedly the hemorrhage proceeded from the iris-vessels; the manner in which the blood oozed out of the iris-tissue sufficiently indicates that such was the fact.

At first thought it would be natural to suppose that the lens or its capsule, as the structure most

extensively lacerated by the operation, was the seat of the hemorrhage. Arlt* mentions having seen in a few cases blood-vessels developed upon the anterior capsule. Ruetet† describes the same thing occurring upon the inner face of the anterior capsule. When, then, these rare pathological conditions are present it would be very possible for hemorrhage to occur from the needle lacerating the vessel-coats. I have within the past year assisted Dr. Strawbridge in operating upon a case of traumatic cataract occurring in private practice, where this very thing occurred. The first three operations, in which the capsule was very lightly divided, were not followed by any event worthy of note. In the fourth operation the capsule was very freely divided, and a slight amount of blood escaped into the pupillary space, barely sufficient to tinge the aqueous humor; no unpleasant symptom followed, and the lens is now so nearly absorbed as probably not to require another operation. In the case before us the hemorrhage was too large to admit of its proceeding from lacerated capsular vessels, and, further, repeated and most careful examination failed to detect a single vessel upon the capsule; so that the blood may safely be considered to have escaped from some other tissue, and doubtless from the iris, as before stated.

2. As to the cause of the hemorrhage. Was it due to the wounding of the iris-vessels by the needle? Most certainly not: this point was carefully watched in the operations succeeding the first, making it certain that some other explanation must be given.

Was it due to escape of aqueous humor and consequent diminution of intra-ocular tension? Adolph Weber‡ has reported a case of hypæmia in which paracentesis corneæ was repeatedly performed, followed in each instance by fresh escape of blood into the anterior chamber. The exciting cause of the hemorrhage in this case of Weber's, to a certain extent, was doubtless the evacuation of the aqueous humor, but in the case before us so little aqueous humor was lost, if, indeed, any escaped, as practically to make this explanation insufficient.

Before giving what I believe to be the true explanation of this case, allow me to call attention to a few points which have a bearing upon it.

1. The origin of this cataract. The youth of the patient, the absence of any history of injury to the eye, the vitreous cloudiness, the absence of morbid change in the left eye, lead to the conclusion that the cataract was the result of inflammatory action involving one or more of the neighboring tunics of the eyeball.

2. An engorged condition of the choroidal veins readily induces hyperæmia of the iris, sometimes so excessive as, upon slightly increased afflux of blood to the part, to cause the escape of blood into the anterior chamber. Such, doubtless, was the explanation of the case of Weber's, in which the patient by the mere act of bending the body forward was able to bring on the hypæmia.

Other cases of this kind might be cited, were it

* Die Krankheiten des Auges, Bd. ii. S. 263.

† Lehrbuch der Ophthalmologie, ad loc.

‡ Archiv für Ophthalmologie, Bd. vii. Abth. i. S. 59.

necessary. Moreover, the interesting researches of Leber* have shown that after ligating the *venæ vorticosæ*, the principal channels of return for the iris-blood, marked hyperæmia of the choroid and iris sets in, which is followed by extensive infiltration of the tissues by red blood-corpuscles, which appear, in accordance with Cohnheim's views, to have passed through the vessel-walls. On allowing the ligatures to remain a short time, small collections of blood take place upon the iris, ciliary processes, and in the anterior chamber, dependent, probably, on the rupture of vessels of small calibre.

3. The corneal puncture in the operation of discission is followed by an almost instantaneous injection of the conjunctival and sub-conjunctival vessels, lasting generally from one to two days, indicating that the operation, simple though it be, calls forth sufficient irritation to induce an afflux of blood to the part.

Basing, then, the exposition upon these points, I may formulate it as follows: previous to his application to us, an inflammation had occurred, originating very possibly in the choroid, but involving secondarily some of the neighboring structures, with resultant disturbance of the nutrition of the lens and formation of cataract. Further, in consequence of the disturbance of the intra-ocular circulation, an engorged condition of the iris-veins resulted, sufficient upon slight afflux of blood to rupture their coats. This afflux of blood we believe to have been caused by the irritation of the discission.

There remains yet an interesting feature of this case to discuss, viz., the rapidity with which the blood was absorbed: in from twenty-four to thirty hours every trace of it had vanished from the anterior chamber. It is interesting to note the time required for blood-absorption in the anterior chamber in different cases.

Years ago,† Meyer called attention to the fact that in wounds of the eye by which the aqueous humor is totally evacuated and blood occupies its place, the latter will sometimes be absorbed in twenty-four hours.

In cases where the eye has been injured by an impinging missile, which, without penetrating the ball, has yet caused an escape of blood into the anterior chamber, it is not uncommon for it to require days and even weeks for its removal.

I have recently had under observation two cases of this kind. In one the eye was struck by the cork of a mead-bottle, which was driven forcibly out by the accumulated gas. Although the blood in the anterior chamber was small in amount, it required at least five days for its removal.

The other patient was a quarryman, who, while sledging, was struck by a small fragment of stone with such violence that, without penetration of the ball, a large amount of blood was poured out into the anterior chamber, the latter being, when I saw it two days after the accident, two-thirds full. In this case more than two weeks were required for the blood-absorption.

This variation in the time required for the blood-absorption is explained by several circumstances which hardly need be specified. There is time merely to call attention to the most important one of all, viz., the condition of the absorbing vessels as regards this fulness, and the rapidity of the fluid contained within their walls. According to well-known physiological laws, venous absorption is accelerated by increased rapidity of the blood-stream, but retarded, or even stopped, according as the current is slowed or stasis takes place. Practically, we may consider the main absorbents in all these cases to be the vessels about the sclero-corneal circle and the venules of the iris, and particularly the fine net-work of vessels overlying the iris first described by Leber, to whose investigations concerning the vascular systems of the eye we owe so much. Let us then apply this fact to the cases before us. In the case forming the subject of this paper, a passive hyperæmia of the iris dependent upon disturbance of the choroidal circulation was present. The local depletion afforded by the hemorrhage was sufficient for the time being to relieve the embarrassed circulation, and to admit of rapid absorption. In the other cases a violent active hyperæmia was called forth by the injuries, and at the time of application for relief, in one an acute iritis was in full blast, in the other a condition closely bordering upon it. The effect, then, of the hemorrhage was but momentary as regards the condition of the vessels; redistention of the vessels quickly ensued, the blood-current was slowed, and rapid absorption stayed.

The interesting features, then, of this case were the hemorrhage, sufficiently large in amount to fill the anterior chamber, resulting from the operation of discission performed through the cornea, and the rapid absorption of the escaped blood.

1535 PINE STREET.

NOTES OF HOSPITAL PRACTICE.

PHILADELPHIA HOSPITAL.

CASE OF MITRAL AND TRICUSPID DISEASE, WITH EMBOLISM.

Reported by Dr. JOHN GUITÉRAS.

DURING my term as resident physician to the Philadelphia Hospital, I had under my care, in the wards of Dr. William Pepper, the following case, which may prove of interest to the readers of the *Times*.

Mary W., æt. 35, temperate; admitted May 7, 1874. Family is healthy, excepting the mother, who died of heart-disease. The patient has never had rheumatism or syphilis.

Though not a strong woman, she has been working for many years at the sewing-machine, without any other symptoms than occasional slight palpitations of the heart, epistaxis, and frequent bronchial catarrhs. For years she has had an eruption of *acne rosacea* over the face. She has never had dropsy.

She was working up to three weeks before admission, when she had an attack of hemiplegia, with sudden loss of consciousness, and complete paralysis of the whole left side of the body. Since the attack there has been oedema of the affected side, and, though motion has been gradually returning, she cannot yet help herself at all.

* Archiv für Ophthalmologie, Bd. xix. Abth. ii. S. 145.
† Beiträge zur Augenheilkunde, S. 17, Wien, 1850.

On admission, her expression was anxious. There was difficulty in articulating, and the tongue was protruded towards the left. There was no paralysis of sensation, and the electro-muscular contractility was good. The veins of the hands were distended, and there was almost complete absence of radial pulse. On auscultation we could hear a few distinct beats, followed by a series of such rapid, abortive pulsations that they could not be counted. A mitral murmur and a clacking sound were also detected. She was ordered five drops of tincture of digitalis, with camphor-water and solution of acetate of ammonia every two hours; also nutritious liquid food and stimulants.

May 9.—In the evening the heart became more regular; by ausculting, its pulsations could be counted 130. The murmur was well defined as a double mitral.

May 10, 3 A.M.—She was attacked with a sudden severe aching pain, which, affecting first the right arm, became at last fixed in the right leg. One-quarter of a grain of morphia, administered by the night-nurse, gave no relief. At 6 A.M. the pulse (as determined by auscultation) is 165, and the respirations 30, short and moaning. The temperature in the right axilla is $91\frac{1}{2}^{\circ}$, and 91° in the left (the thermometer was kept in position for fifteen minutes). The face and extremities are cold and purplish. In the right leg the coldness extends up to the groin. This limb feels to her numb and heavy, but motion is not impaired. Her pupils are contracted, and she is drowsy. I gave her immediately an ounce of whisky, a drachm of tincture of digitalis, and half a drachm of the aromatic spirits of ammonia. She was rubbed with dry hot cloths; the limbs were wrapped in cotton, and hot pans were placed under the bed-clothing. She was ordered to take, every hour, five drops of tincture of digitalis, twenty of the solution of ammonia, with a tablespoonful each of solution of the acetate and whisky. Hot beef-tea was also given in abundance, and some milk.

Every symptom pointed to the existence of a clot in the femoral artery, except that in the dorsum of the foot, and for some distance into the femoral triangle, a pulsation was felt, which was quite puzzling.

At 5 P.M., temperature 98° . Pain was so intense that I gave one-quarter of a grain of morphia hypodermically, and she went into a sound sleep, from which she was with difficulty aroused.

At 7 P.M., pulse 150; respiration 12. Extremities are warm, except the right leg. The expirations are prolonged and snoring, and the pupils much contracted. Says that she feels better.

At 11 P.M., respirations have fallen to 9, and they are rattling. But the pulse is 137, and on waking her the respirations become easier, and they increase to 14. Ordered one-sixtieth of a grain of atropine, which was repeated in three hours.

May 11.—At 5 A.M. the digitalis-mixture gave out, and at 9 the pulse is 150, respiration 27. She feels better, and the temperature continues normal.

Evening.—Pulse 150. During the day digitalis has been given in fifteen-drop doses, but she has been vomiting. A turpentine injection was given to relieve tympany; and eighteen ounces of urine were drawn. She was ordered, for the night, injections of whisky and ammonia, with fifteen drops of digitalis every three hours.

May 12.—Pulse 165; respiration 25. There is but little pain. The right leg begins to show scattered patches of ecchymosis. The foot is paralyzed, and the toes are flexed. The pulsation in the veins of the hand noticed yesterday has disappeared. The simultaneous disappearance of all pulsation in the dorsum of the foot, and subsequently in the femoral triangle, makes me believe that the unaccountable pulsation previously felt in these two places was a venous wave.

Evening.—Respiration 24; pulse 150, not yet to be counted at the wrist. A stupe made with six ounces of the infusion of digitalis was placed on the abdomen at noon, and renewed this evening.

May 13.—She is a great deal better. Respiration 18; pulse 137 at the heart, 69 at the wrist. The toes of the right foot commence to shrivel. She takes food well.

Evening.—Pulse 150; respiration 27. Ordered again whisky in tablespoonful doses every three hours. The stupe was renewed morning and evening.

May 14.—Feels very well. The pulse is between 75 and 100, whilst the cardiac contractions number 135 to 140. The stupe was removed, and fifteen drops of tincture of digitalis were given with the whisky.

Evening.—Pulse 117.

May 15.—Pulse 108 at the wrist. It is pretty regular, and of fair volume. The heart beats 117. The dose of digitalis was now reduced to five drops every three hours.

Evening.—Heart beating 162; respiration 36. (Edema of the lungs soon developed, and she died next morning at 10 o'clock. The recent emboli found in the lungs and brain were the immediate cause of this sudden change in the symptoms.

Post-mortem, 2 P.M.—Rigor mortis well marked. Patches of ecchymosis are scattered over the right leg from the lower part of the thigh downwards. The discolored part is cold, whilst the warmth is yet retained above. The toes of the right foot are dry and shrivelled. Higher up we find bullæ and peeling of the epidermis.

Thorax.—The apex of the heart is in the fifth interspace, just outside of the line of the nipple. There is splenization of the lungs posteriorly. The anterior portion of the right lower lobe is the seat of two quite extensive patches of hemorrhagic infarctus, triangular in shape and with the base towards the pleura. They are quite recent; the two emboli not having yet become attached to the walls of the vessels. There is an extensive area of collateral hyperæmia surrounding the infarctus.

Heart.—The pericardium is normal. The viscus is dilated and hypertrophied to a slight extent. The left auricle is very much dilated. The mitral opening is contracted into a narrow funnel, which only admits the tip of the little finger. The leaflets are calcareous and very rigid. Regurgitation is easily demonstrated by the hydrostatic test. On the auricular surface of the posterior leaflet, towards its base, there is a large ulcer, probably atheromatous, as there are no evidences of acute endocarditis. Its surface is covered with a rather firmly attached, friable clot, evidently the origin of the existing systemic emboli. The tricuspid valves were simply glued together along the edges; but they were perfectly flexible, and gave rise to very little obstruction and regurgitation.

The muscular fibres, under the microscope, appeared slightly granular; but the striation was distinct.

Abdomen.—Liver small, and showing nutmeg pigmentation from red atrophy. The kidneys are the seat of congestive nephritis, evidently chronic, as shown by the induration of the tissues. One of them presents a small infarctus, commencing to break down. The right internal iliac artery is occluded by an embolus; and the mucous membrane of the bladder is congested and discolored by numerous punctated hemorrhages.

The femoral artery and its branches, as far down as I can dissect in Scarpa's triangle, are filled with a dark, rather firm clot. The coats of the vessel are discolored, but the clot is only slightly adherent. The anterior tibial at the ankle is empty.

Brain.—An embolus, similar in appearance to the deposit on the endocardial ulcer, is found at the junction of the middle and anterior left cerebral arteries. It must be very recent, as the blood has not yet coagulated about it. On the ventricular surface of the anterior por-

tion of the right corpus striatum is found a cavity about one-half an inch in diameter. It is filled with the rather thick fluid of fatty debris. Probably these are evidences of yellow softening following a condition of red softening.

The urine was highly albuminous, and deficient in urea. It contained rare epithelial casts, and some highly granular. There were also found very few hyaline and hyaline-epithelial casts.

TRANSLATIONS.

A REMARKABLE CASE OF LUXATION OF THE PENIS (Dr. Moldenhauer: *Berliner Klin. Wochenschrift*, No. 45, 1874).—Luxation of the penis on account of a loose connection between the skin and the corpora cavernosa is an accident which may occur, although it is not often met with. One case is reported by Nélaton, and mentioned by Hyrtl in his work on topographical anatomy. The patient in this case was a boy who was injured by the caving in of an embankment, the skin enveloping the penis being torn from its attachment, thus allowing that organ to slip under the skin of the scrotum. The displaced organ was in this case returned by means of a forceps introduced into the preputial opening.

The case described in this article is still more remarkable, since the penis was torn completely from its enveloping skin and thrust beneath the coverings of the abdomen.

W. K., a strongly-built farmer, aged 57, was injured on the 25th of October, 1867, by falling from his wagon. As he got up, the horse forced him against a tree, and the hind wheel of the wagon passed close in front of his body, and he found that he was severely hurt. Upon examination, it was found that the symphysis, scrotum, and penis were covered with blood, and that the scrotum was much swollen and filled with extravasated blood. There was no fracture of the bones of the pelvis, and no injury of the abdominal organs could be found. The penis, however, was much injured; the glans could not be recognized, and the whole organ hung soft and flaccid as if it had been completely crushed, but it was not very painful upon manual examination. In order to make out the condition of the urethra, an effort was made to introduce a catheter, but without success, for the instrument, after repeated trials, could only be passed as far as the symphysis pubis, where its further progress was arrested. The patient was placed in bed, and compresses, soaked in lead-water, applied to the injured parts. During the night no urine passed from the penis, but it was found that there had been extravasation of that fluid into the scrotum, which was much distended and emitted a urinous odor. As it was now evident that some operative interference was necessary, the patient was placed under the influence of chloroform, a catheter introduced as far as possible into the urethra, and an incision made down upon it through the raphe of the scrotum. The tissues were now dissected away, layer by layer, and careful search made for the urethra, in which the catheter was supposed to lie; but that passage could not be found, and, owing to an attack of hemorrhage of a violent character, further investigation had to be desisted from. On the same evening the patient was quite comfortable, the urine flowed freely from the scrotal wound, and, with the exception of the burning which it occasioned in its passage over the raw surfaces, caused him no annoyance.

On the 30th of October a new effort was made to find the urethra. The first incision was continued up to the root of the penis, and there was found to be beneath

the symphysis a cavity filled with ragged tissues and granulations, into which an elastic catheter was thrust to the extent of an inch or two, but no further introduction of the instrument was possible.

On the 6th of November an abscess formed in the abdominal walls, on a level with the spine of the ilium, which was opened the next day, discharging pus very freely, and having a fistula whence much more urine came than from the wound below in the scrotum.

On the 10th of November another unsuccessful search was made for the urethra, and then for the first time the idea arose that this must be looked for in the upper portion of the inguinal region.

A catheter was introduced into the superior opening, which passed down to the opening under the symphysis; and on the 12th an incision was made in the inguinal region, and the penis, deprived of its skin, but in other respects uninjured, was found lying imbedded in the fat and connective tissue covering the muscles of the abdomen. The entire penis had therefore been torn from its cutaneous sheath, and had then slipped up into the inguinal region beneath a portion of the layers composing the parietes of the abdomen. The urethra was uninjured: a catheter could be passed from the meatus through the organ, which had formed adhesions to the abdominal muscles up to the symphysis, where its farther progress was arrested. The glans and prepuce were dissected off, but, at the request of the patient, who stated that he only wished the penis for the function of urination, no further attempt was made to restore the organ to its normal state. That which had been regarded at the time of the injury as the crushed and bruised penis was composed only of the cutaneous envelope of that organ, the deeper portions of which had, as has been described, escaped up into the walls of the abdomen. The wound finally healed, the penis up to the glans being adherent to the muscular structure of the part and covered with skin. The glans itself was left bare and movable, so that the patient can urinate with no trouble. Erections occur from time to time, but are attended with no pain, and the man is very unwilling to have any further operative measures undertaken.

THERAPEUTIC NOTES.

EXPECTORANT POTION.—

℞ Apomorphiæ chlorohydrat., $\frac{1}{2}$ to $\frac{1}{2}$ gr.;
Aq. destillat., ℥iii;
Acid. hydrochloric., gtt. v;
Syrupi simplicis, ℥i.—M.

Sig.—Tablespoonful every hour.—*Bull. Gén. de Thérap.*, October 30, 1874.

INTERMITTENT FACIAL NEURALGIA.—

℞ Quiniæ sulph.,
Tinct. aconit., āā gr. xx;
Pulv. quiniæ, q. s.—M.

Ft. in pil. no. xx.

Sig.—Three or four immediately on accession of the attack.

CALMATIVE EXPECTORANT.—

℞ Syr. acaciæ, f℥iv;
Antimonii oxysulphuret., gr. vi;
Ext. opii,
Ext. belladonnæ, āā gr. ii.—M.

Sig.—Tablespoonful every two or three hours in acute catarrhal bronchitis with fits of dry coughing.

PHILADELPHIA

MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JANUARY 2, 1875.

EDITORIAL.

BILLS.

IT is now the season when physicians, in corpora vili or by proxy, are engaged in making out their semi-yearly or yearly accounts; so that a few editorial comments upon professional bills may not be out of place. In this city, at least until within a few years, doctors only rendered their accounts once annually, but we trust there is not one of our readers who still cleaves to this time-honored but indefensible and injurious practice. There is no reason why doctors should wait for their money so much longer than do tradesmen. Moreover, a bill that might have been paid willingly when the memory of the recent peril and of the physician's skill and kindness was still fresh, is often paid very grudgingly when time has worn away the vividness of the impression. Again, no prudent man likes to have bills accumulating by the year unchecked; better at least once in six months to take an account of stock and square off indebtedness: therefore we believe most patients really prefer a semi-annual rendering of their accounts to an avalanche at the end of the year.

Undoubtedly, to most men it imparts more of a sense of strain to pay five hundred dollars in January than to pay two hundred and fifty at the end of each six months.

Among the lower classes very many bills are unquestionably lost by being allowed to accumulate, and we therefore note with pleasure that a few of

our physicians are beginning to send to such patients monthly accounts.

There has recently been handed to us an old medical bill, stated to have originated in one of the small Jersey towns. We are assured that it is genuine, and the peculiarities of the paper, spelling, etc., bear testimony to the same effect. We print it below in contrast with a modern model, partly as a curious relic, and partly because we think that in some respects it is a more proper and just bill than are those at present usually rendered:

For professional services		\$200.00
Jan. 1, 1875.		

Not long since, we heard a prominent physician say that he considered it a gross insult for a patient to ask him for a bill of items. It seems to us, however, that the only just and proper bill is one of items. Why should not the number of visits be specified? Has not the patient a right to know at what rate he is paying? Must a physician's account always remain an unknown and unknowable charge against the patient until it is rendered? The only possible object that can be gained by the physician is that sometimes he is able to charge at a rate which the patient might not willingly pay if he knew it. But is this just? Moreover, very often the patient believes that he is charged at a higher rate than he really is, forgetting how rapidly visits, when paid several times a day, mount up.

Some will say, "But a doctor is not a tradesman." True, but money is money, and business is business. True business principles are those principles which experience has evolved as being just in the

dealings of men with one another. The sooner the profession gives up all false notions of professional dignity and conducts its business relations with the people in a business-like manner, the sooner will those relations become satisfactory; and there is no principle more firmly established and more evidently just than the right of a man to know exactly what he is paying for, and at what rate.

We have always held it to be an absurdity for all doctors to charge at the same rate. Dr. Smith at thirty is not worth so much as he is at forty; and precisely as other professional men are paid,—variously, according to their reputations,—so ought doctors to be. The result of the present system is that at thirty the physician is almost starving; at fifty he is working like a galley-slave to save a little in order to pay his back debts and accumulate something for old age; whereas, if at thirty he charged two dollars per visit, and five dollars at fifty, at thirty he would have a comfortable living from the lighter cases of disease and from persons who could not afford the higher price, whilst at fifty, with no back debts to pay and something accumulated, he could live like a gentleman, earning a fair income by a reasonable amount of work. It is, however, not right to charge heavily without giving warning. Dentists in this city print upon their engagement cards, "Charges, ten dollars per hour;" shall we ever have the good fortune to see a doctor in Philadelphia bold enough and honored enough to print upon his bills, or write upon the face, "Charge, five dollars a visit"? A man may justly grumble at a very large charge which he has not expected, but no man has a right to grumble at any bill which he knowingly incurred.

BOGUS DIPLOMAS—MURDER.

FROM swindling to murder is but a few steps; especially when the swindling involves abetting those who are *nominally* swindled in becoming murderers. We suppose, therefore, none of our readers have been or will be surprised at the recent abortion so closely connected with a medical college owned and managed by the well-known and estimable Dr. Paine. Curiously enough, the abortion was produced at a house which has been the home of successive regular practitioners of excellent repute for very many years, until it passed into the hands of Mrs. Mixter and colleagues. The case, as far as made out, is briefly as follows. A young woman was brought, some few days since, from Conshohocken to this house, and an abortion produced by some one as yet unknown, from which she died last Wednesday (December 16). On Thursday

the detectives in some way got wind of the affair, and by Friday had obtained such information that they called upon the worthy doctor already mentioned, and asked if he knew anything about a body recently brought to his college. With the blandest courtesy, the learned professor stated that he did not; but, on the twain going to the institution, the janitor informed them that a Dr. F. C. Perpente, or Dr. Dubois, as he is variously named, had brought one into the college the day before. The dissecting-room was next visited, and the body was found, not as yet injected or in any way injured, but showing, it is said, very decided traces of criminal abortion. Dr. Perpente was arrested at his office about midnight the same evening. On going to Mrs. Mixter's house, it was found vacated, the bird having suddenly flown, taking seemingly only clothing and money, leaving everything else in the house just as last used. Of course Prof. Paine denies that Dr. Dubois had any connection with the institution; but, unfortunately, his name appears upon the official printed card.

CORRESPONDENCE.

NEUROLOGICAL SOCIETY OF NEW YORK.

NEW YORK, December 9, 1874.

AT a recent meeting of the Neurological Society, Dr. F. D. Lente, of Cold Spring, N.Y., read an important and lengthy paper upon "The Neurotic Origin of Disease, and the Action of Remedies on the Nervous System," of which the following is a very brief abstract.

For some years past his own experience had impressed him with the belief that in most diseases, especially those of an acute character, the morbid impression is first made on the nervous system, either directly, as in the case of the mucous membrane, where the peripheral nerves are more accessible to the immediate action of toxic remedies, or *indirectly*, through the medium of the blood; that the remedies, therefore, most likely to exert an abortive effect on disease, or, where that is not attainable, the speediest and happiest relief, are those which are supposed to act especially on the nervous system; and that our ordinary treatment, by acting in a more indirect and therefore less speedy manner, as well as by disturbing other portions and other organs of the body not involved in the morbid process, is slower, less certain, and more unpleasant in producing these curative effects.

He classed among diseases of a neurotic character "malarious" fever, and especially the intermittent form. He had no theory as to the causation of malaria to offer, but, whatever the cause may be, it seemed to him to act primarily on the nervous system, and its morbid energy to be most expended in its assaults on that system. The

evidence advanced, both from the arguments and data of those adopting a certain theory of causation and of those virulently opposing it, alike tends to support this idea. Thus, it is admitted that repose, and especially repose at night, renders the body most liable to miasmatic influence, while exercise, even in what is supposed to be the hot-bed of poison, is preventive. Every one knows how much more liable we are to "take cold" when sleeping, or even when in a drowsy state, and especially at night, unless the body has an additional covering, and how great a protection exercise is. In both cases the nervous system is more impressible in the one state than in the other. Exercise and occupation in all epidemics of whatever kind are the great preventives. Indolence and fear, causing greater nervous impressibility, are our worst enemies. The sudden onset of the disease points to the primary affection of the nervous system.

He also instanced articular rheumatism as an example of a neurosis. Dr. J. R. Mitchell attempts to prove it a neurosis, and refers its phenomena to a spinal origin. In a case of pruritus reported in the first number of the *Archives of Dermatology*, by Dr. Beard, for Dr. Kinsman, of Ohio, the latter remarks, "The moment the current (of electricity) is passed along the spine the pruritus ceases." Dr. Beard also reports a case of herpes zoster frontalis for Dr. Bulkley, cured by galvanism. The spinal origin of many cutaneous affections is well established. It is important, in all cases of very obstinate eczematous or bullar diseases, to pay special attention to the influence of the nerve-centres and of possible nerve-lesions as a cause.

The peculiar effects of cathartics, especially where they are given for their so-called derivative action, can only be explained by this reflex influence on the brain and its vaso-motor vessels rather than by unloading the abdominal vessels, since the impression felt in the brain is almost instantaneous. This is felt sometimes even after an ordinary evacuation, or even after the passage of a gas.

Dr. Lente then proceeded to review the physiological effects of the more important remedies, among which he mentioned atropia, ergot, strychnia, opium, conium, physostigma or ergotine, iodine, calomel (in sedative doses), quinine, phosphorus, amyl nitrite, the bromides, the anæsthetics (by inhalation), digitalis, and electricity.

We cannot review these remedies in detail, but shall only reproduce a few of the author's thoughts here and there. He thinks that comparatively few physicians, taking the whole country, have any definite idea of the value of digitalis as a heart-tonic. The error has probably arisen from noting its effects on animals in toxic doses. In such doses "it lowers reflex action, and induces lassitude, prostration, muscular tremblings, and sometimes convulsions." It produces such an energetic action on the heart, if pushed too far, "that the ventricles become white as the last drop of blood is squeezed out of them." Finally, if pushed to its poisonous effect, the heart is arrested in systole (H. C. Wood).

In regard to the action of the bromides, there is one

rather wide-spread error which tends greatly to circumscribe their usefulness, namely, that in cases of cerebral anæmia, or in a condition of the circulation in which it may be supposed that this exists, they are useless, and even injurious. Now, the result of experiments with these drugs on animals, carefully collected, as well as those of clinical experience, go towards demonstrating the fact that the least important of the effects of these agents is their vaso-motor influence; that their most important action is in controlling and, if pushed far enough, almost obliterating reflex action,—first, by a direct effect on the nerve-centres, the medulla oblongata, and the cord especially; secondly, on the peripheral nerves: that is, blunting the susceptibility of the latter to painful impressions, and also the susceptibility of the cord as to those impressions. This important virtue of the bromides is well exhibited in preventing sea-sickness and the vomiting induced by anæsthetics, and the unpleasant effects of opium and quinine, which clinical experience has recently taught us. This property has special applicability in the treatment of certain functional diseases of the heart.

As regards the use of the active neurotics, it is certain that most of the failures and disappointments often complained of have resulted from inefficient doses. We may give this as a rule of action, that the drug cannot be said to have had a fair trial unless it has relieved the symptoms or produced its toxic effects. With regard to the bromides, strychnia, opium, atropia, physostigma, this is especially the case; and in very dangerous cases the toxic effects need often to be very pronounced. The doses, in fact, are as various as the temperaments and idiosyncrasies of the patients. For an account of the employment of large doses of physostigma, reference was made to the last number of the *London Practitioner*. The patient, a physician, took, in four days, of the solid extract of a reliable manufacturer, sixteen, forty-eight, fifty-seven, and seventy-two grains at one time; serious paralysis was induced, but the urgency of the disease, tetanus, required a perseverance with the drug.

ODONTOLOGICAL SOCIETY OF NEW YORK.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—This body, comprising the representative men of the dental specialty of New York City, has just concluded a meeting of three days' duration, during which were presented and discussed a series of elaborate essays such as would be a credit to any professional body that might assemble in the country. At this meeting were collected as guests of the Society quite a number of the prominent teachers connected with the different dental colleges, together with gentlemen from different sections of the United States, most distinguished in the various departments of the specialty.

The subject of professional education and practice, which was discussed with unusual warmth, exhibited

markedly the inclination entertained for a wider sphere of work, and portrayed plainly enough that the conversion of the dentist into the oral surgeon is only a question of time.

The ranks of the common mother-profession would receive a valuable addition in such gentlemen as compose the New York Odontological Society, and we most cordially unite with a speaker from your own city in trusting that the day is not distant when all shall be children of one alma mater, working in harmony and with a mutual interest for the common good of suffering humanity.

M. D.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THE PRESIDENT, DR. WILLIAM PEPPER, in the chair.

THURSDAY, NOV. 12, 1874.

CANCER of the uterus.

Dr. JOHN H. PACKARD presented the specimen, derived from a woman aged 49, whose history has been published in the *American Journal of the Medical Sciences* for July, 1874, as "*A Case of Lumbar Colotomy for Obstruction of the Rectum by Cancerous Tumor of the Uterus.*" The object of the operation was the temporary relief from the obstruction, and by its means much comfort was secured to the patient while she lived, which was thirty-four weeks.

Dr. JOHN S. PARRY desired to know some further particulars of the case.

Dr. PACKARD said that when he first saw the patient her vagina was filled with a growth, and an examination of the uterus by the speculum was difficult, on account of the extreme vascularity of the mass distending the vagina. On introducing the finger into the rectum, it was arrested in a short time by a mass which appeared to block up the pelvis and make any further examination of the pelvic organs difficult. The operation of lumbar colotomy was performed, to relieve her from the effects of impaction of the feces. He could not say whether the cancer originated from the pelvic organs or the vagina.

Dr. PARRY asked whether any growths were removed from the vagina.

Dr. PACKARD replied that there had not been any removed in this manner. He further said that the patient lived thirty-four weeks after the operation in comparative comfort, all the horrors of lumbar colotomy, as usually described, having been avoided. There was no odor about the patient, nor any difficulty in keeping her person clean.

Dr. PARRY said he had made a somewhat hasty examination of the specimen. Upon passing the finger up the vagina, which has not been opened, it felt perfectly healthy. The posterior portion of the cervix appeared to be absent; but he could not detect any destruction of tissue with the finger. The external os admits the finger, which may be carried as far as the internal os, where it meets with a constriction. Behind the uterus, between it and the rectum, there appears to be a tumor, which possesses some of the characters of an inflammatory deposit. If cancer of the uterus, it was different from any other he had ever seen. It reminded him of a specimen which had been presented at the Obstetrical Society, as cancer of the uterus, in which he had suspected an error of diagnosis, and in

which careful dissection and microscopic examination proved that the condition was one of pelvic peritonitis.

Dr. PACKARD said he would be very glad to have the specimen referred to a committee for examination. He had spoken of it as cancer, because, in the first place, there was a distinct, readily-bleeding mass in the vagina, which made the examination difficult and rendered the use of the speculum impossible; in the second place, if there ever was a patient who exhibited the so-called cancerous cachexia, this certainly was such a one; finally, notwithstanding the relief to certain symptoms by the operation of lumbar colotomy, the disease swept on without any abatement, and the whole history of the case was that of one which runs its course without the possibility of any treatment materially influencing it.

Dr. JAMES TYSON rose to refer to a subject which had already been much discussed in the meetings of the Society,—that of cachexia. He said that it seemed to have been pretty well determined that the condition commonly called *cancerous cachexia* was one which was very often absent in cancerous disease, and which was sometimes observed when nothing like cancer was present to account for it; that while cancer only involved those organs which were not highly vital, *i.e.*, not closely essential to life, as is the case with many external organs, and perhaps some of the viscera, as the bladder, its presence did not result in the production of the so-called cachexia, while, when organs so important to life as the lungs or liver became involved, the phenomena sooner or later appeared. He inquired of Dr. John Ashhurst, Jr., who had always taken much interest in the subject, whether, consistently with these facts, this was not a case in which we would not have expected the cachexia to attend.

Dr. ASHHURST said that he thought that "cachexia" could no longer be considered an important symptom of cancer, it being well known that cases of *external* cancer might run their course to a fatal termination without any development of cachexia, while, on the other hand, this condition might occur in connection with visceral disease other than cancerous. He referred, in illustration, to a case reported by himself to the Society,* one of primary cancer of the bladder, in which the development of the so-called "cancerous cachexia" coincided with the occurrence of pulmonary disease, which, after death, was found to have been of a non-cancerous nature. The notion that any definite cachexia attended the growth of cancer should, he thought, be given up, and nothing but a careful microscopic examination allowed to determine as to whether any particular tumor was or was not of a cancerous character. In fact, since Virchow and other modern pathologists now described under the name of sarcomata many growths formerly regarded as cancerous, the diagnosis of these growths had come to be purely one of minute anatomy,—the *sarcomata* exhibiting cells in constant relation to an intercellular substance, but the *carcinomata* showing no such relation, while mixed growths were designated as *carcinomatous sarcomata*. If, however, the term *cancer* was used in a clinical sense, as merely equivalent to malignant tumor, it would, of course, include many growths besides the *carcinomata* of anatomical classification.

Dr. PARRY said that, in illustration of Dr. Ashhurst's remarks, he had under his care, at the Philadelphia Hospital, a case of cancer of the uterus, which had destroyed the whole of the anterior wall of the vagina and the posterior wall of the bladder, as well as involving the rectum and producing stricture of that organ. The patient had had profuse hemorrhages during the last few months, and yet there was no evidence of

* Trans. Path. Soc. Phila., vol. iv. p. 157.

cachexia. He had frequently seen cancerous disease run its course in organs not necessary to nutrition, without manifesting these phenomena. In the same ward with the woman whose case he had just related, was another, who came into the hospital with a huge pelvic abscess discharging into the vagina, and accompanied by profuse metrorrhagia. When he first saw her and heard her history, he thought her disease cancerous, and he was led to believe it on account of the cachectic appearance of her skin.

Dr. JOSEPH G. RICHARDSON said that, in connection with this case, he would mention that of a patient of his who died of primary cancer of the ovary, but who would never consent to an examination. As he visited her day after day, he observed, six weeks before her death, the condition formerly described as the "buck-wheat-cake" hue, in a small spot just between the eyes. This patch gradually spread, and three weeks before her death the cachectic appearance was as well marked over the whole face as he had ever seen it in his life.

The specimen was referred to the Committee on Morbid Growths, which reported December 11, 1874, as follows:

"Your committee find the tumor presented by Dr. Packard distinctly alveolated, therefore carcinomatous. Long club-shaped cylinders filled with epithelial cells are seen permeating the muscular layers in every direction: hence the variety is *epithelial carcinoma* or *carcinosarcoma*.

"The same histological features are possessed by the rectal masses and those strewn throughout the body of the uterus and appendages. Greater part of the cervix has been destroyed; whether it or the rectum was the primary seat of the disease remains to be decided upon by the special committee."

Dr. PACKARD presented also a tumor of the thyroid gland, removed by him on the same morning from Mrs. M., æt. 42, who had suffered from it ever since the birth of her second child, nineteen years previously. Within the last year it had been increasing rapidly in bulk; she had suffered much annoyance every winter from it, as well as whenever she took cold or upon making any exertion. The operation was done at her earnest desire, and was in itself not difficult, although the hemorrhage was profuse immediately afterwards and required very prompt and energetic action. The tumor was presented in order that it might be referred to the Committee on Morbid Growths for examination.

(NOTE.—The patient progressed favorably until the seventh night, when there was slight bleeding from the effect of an irritative cough. Congestion of the lungs, which had been previously somewhat troublesome, now became extreme, and she died twenty-four hours subsequently.—P.)

The tumor was referred to the Committee on Morbid Growths, which reported Dec. 11, 1874, as follows:

"The tumor of the thyroid gland removed by Dr. Packard is an ordinary *struma hypertrophica*, with commencing colloid degeneration. The glandular follicles of the parenchymatous substance have evidently been undergoing active proliferation and segmentation, as shown by the budding-out of small glands from the walls of the larger parent follicles. Many of these follicles contain, besides their epithelial lining, a thick, amber-colored, gelatinous or colloid substance. The size of the distended follicles is very variable: in no place, however, have they coalesced so as to form large cystic cavities. The blood-vessels of the fibrous septa are very abundant and large, but the connective tissue itself is only developed in a very subordinate degree,—not sclerosed. In many places the net-work of vessels had a peculiar glassy appearance, their walls being unusually thick, and, upon the addition of iodine, yielding a distinct amyloid reaction. We have, therefore, a

struma gelatinosa, with partial amyloid degeneration of the blood-vessels."

Myxomatous neuroma of the brachial plexus.

Dr. R. M. BERTOLET presented this tumor, which was removed, Nov. 1, at the necropsy of a woman aged 67, who died from pulmonic phthisis. This growth, considerably larger than a fist, completely filling up the right axilla, never gave rise to any pain or decided inconvenience. It was several years in attaining its present size; the integument remaining freely movable over it, while its soft and fluctuating contents were suggestive of a cyst.

Upon dissecting out this fusiform growth, it was found that the nerve-sheaths formed a continuous covering over it, the nerve-bundles and individual fibres being widely separated and spread out over the tumor, and partially imbedded in it. When cut into, it presented a soft, trembling, gelatinous mass, yellowish-white in appearance; the more vascular portions having a reddish tinge and firmer consistence. In the fresh condition the substance of this tumor was not only soft and yellowish, but translucent; the alcohol has rendered it slightly opaque and more solid.

Microscopically, the growth is characterized, as can be seen in the accompanying slides and drawings, by large *stellate* and *spindle cells*, freely anastomosing with one another. These cells are imbedded in a structureless, hyaline basis-substance, which is rendered cloudy and granular upon the addition of acetic acid and other reagents. Septa of connective tissue are only sparsely developed. At points, large oil-globules are met with; at others, again, small round mucoid cells fill up the meshes; but the bulk of the growth presents the above pure type of myxoma.

Histologically, there can be no doubt that we have here a tissue analogous to embryonal connective tissue, which has sprung from the perineurium of the brachial plexus. It is not a neuroma in the true sense of the word, the term being admissible only in so far that it is indiscriminately applied to all neural tumors. Even the painful neuromatous growths so often occurring after amputations are generally mere fibromas, an actual new growth of the nerve-fibres themselves being exceedingly rare. Most of the spindle-shaped tumors found along the trunks of the nerve belong to the class of myxomas, as has been long ago pointed out by Virchow. When thus situated they are often multiple, and give rise to neuralgia and lancinating pains; yet they may fail to evoke any of these symptoms, as in this instance. Virchow mentions a case in which a painless myxomatous growth seated upon the peroneal nerve was mistaken and opened for a hygroma.

Myxomatous neuromas, like the myxomatous growths occurring in other portions of the body, are comparatively benign, with perhaps even still less tendency to metastasis. After the peripheral nerve-trunks, the next most frequent site for these neoplasms is the spinal cord; while in the brain and its meninges they are the exception, the pathological production of the cerebral neuroglia being the glioma.

Multiple myxoma of the spinal cord.

Dr. BERTOLET also presented these growths, which were discovered accidentally upon the cord of an adult of whom no clinical history seems ever to have been obtained. They are five in number, scattered along the length of the cord, both upon its anterior and posterior surfaces. The largest measures nearly half an inch in length, but only a few lines in thickness. The microscopic appearances do not differ materially from those of the preceding specimen.

The PRESIDENT asked what was the relation of the nerve-fibres to the tumor.

Dr. BERTOLET replied that the nerve-filaments were spread over the surface of the tumor first presented.

The PRESIDENT said that about a year ago he had the opportunity of studying carefully a myxoma removed from the right supra-spinous fossa. It was not nearly so large as this specimen, but presented the same microscopic characters.

The point of origin was not determined, but it was not connected with any twigs of nerves, but appeared to occupy a superficial position in the subcutaneous cellular tissues, being invested by a delicate fibro-cellular sheath.

The PRESIDENT remarked upon the presence of Dr. J. J. Woodward, of the army, who had been one of the original members of the Society and most active in its proceedings, and invited him to make any remarks which his large experience in the histology of morbid growths might suggest.

Dr. WOODWARD said that it would give him great pleasure to say something on the subject, if he thought he could add anything to what had been so well said by the members who had already spoken. He assented to the opinion that these growths are rare; certainly he had seen comparatively few of them. The only point not mentioned by previous speakers which it occurred to him to mention was the occasional association of myxoma with genuine carcinoma in the same growth. Not long since, he had examined such a tumor at the Army Medical Museum. It was from the parotid region, and for the most part consisted of typical myxomatous tissue, with beautiful stellate cells. A portion of the growth, however, had the anatomy of carcinoma, and presented a true alveolar structure, the alveoli being stuffed with masses of granular cells with large nuclei, which adhered together without any intercellular substance. Several of the microscopical sections preserved exhibited both these forms of morbid tissue in different portions of the same section.*

Perforation of vermiform process by ulceration, and resulting acute diffuse peritonitis.

Dr. W. H. WARDER presented the specimen, for Dr. EDWARD STONE, from W. B., æt. 24 years, married, temperate, and who had always enjoyed good health previous to his last illness. Dr. S. was called to see him on the evening of Oct. 24. He said that he had had "cramps" all day, for which the ordinary domestic remedies were taken,—ginger, brandy, etc.,—but without much relief. His bowels had been moved twice that day, and he had had nausea and some vomiting during the afternoon. He was suffering at the time of the visit from severe pain in the umbilical region, which came on in paroxysms every few minutes, and was not relieved by pressure, although the belly was not sensitive to pressure. Tongue slightly coated; pulse 80, rather small and weak.

Oct. 25, morning.—Considerable vomiting during the night. Pain has been relieved, but considerable tenderness has been developed generally over the abdomen, not sufficient, however, to prevent him from leaving his bed to go down-stairs. The soreness is most marked between epigastrium and umbilicus. No *tympanitis* whatever. Has no pain, excepting when turning in bed, and the position of lower extremities has no influence on it. Tongue heavily coated in the centre. Respirations hurried and somewhat superficial; pulse 98, small and weak, and considerable heat of skin.

Oct. 25, evening.—Vomiting has ceased. Although "he feels better," and is comfortable while lying still, he is much weaker. Pulse running 120, and very small

and compressible, with marked heat of skin. Respiration entirely thoracic. No tympany, the belly looking natural as before. Lying on his back, with limbs extended. Bowels have not been opened since yesterday. Retention of urine; catheter was passed, and about a half-pint of urine withdrawn, normal in appearance.

During the night he sank rapidly, and died at 7 A.M. Oct. 26.

(After his death, Dr. Stone learned that he had been ailing and had had "pain in his stomach" for several days before he saw him.)

Autopsy, twenty-six hours after death.—*Abdomen* only examined. Rigor mortis well marked. Abdomen flat. Signs of violent acute peritonitis, involving the whole sac. *Omentum* swollen and injected, and glued down by recent adhesions to surrounding viscera. *Intestines* congested and matted together, covered here and there with patches of soft yellow lymph. In right iliac fossa, the caput coli and lower portion of ileum were more firmly adherent, and were thickly covered with lymph. The vermiform appendix was firmly adherent to an adjacent coil of intestine by its extremity, and was about the diameter of the index-finger, patulous, and full of semi-fluid fæces. Near its base a small ulcer was found to have perforated the bowel. The mucous membrane of the intestinal canal elsewhere was not ulcerated. No foreign substance was found, and the fæces in the colon were healthy. Peritoneal cavity contained about one-half pint of sero-purulent fluid.

The PRESIDENT said these cases were of interest and importance, in consequence of their being much more frequent than is usually acknowledged, on account of their fatality and the obscurity of their diagnostic symptoms. In this unfortunate case one would suppose from the size of the appendix that there had been latent disease of a chronic inflammatory character, so that the true period of beginning of the typhlitis was not observed, while the disease was rapidly going on to perforation. Indeed, typical symptoms can scarcely be said to have manifested themselves. The case was also of interest from the fact that there appeared to be no foreign body or hardened secretion of mucus occupying the appendix, as is usually the case, though, from the fact that there was still free communication between the appendix and the cæcum, such a body may have existed and have escaped into the large intestine.

In answer to a question by Dr. HARRISON ALLEN, the President further said that in his own observation the position of the ulcer had seemed to be a matter of indifference. He had seen it occupy the extremity of the appendix, and all intermediate points between this and the cæcum. He had seen from two to four ulcers with two perforations. The ulcers often arise in connection with some distinct irritating particle which is at times attached at the site of the perforation, and seems to have been the determining cause of the ulcer at that point. In cases where the opening between the appendix and the bowel is closed by adhesions, the cavity of the appendix is apt to be greatly distended by the accumulation of pus. In cases where the communication with the cæcum is retained, the irritating foreign body may escape from its position into the large intestine, and thus be overlooked. But it would seem that usually the seat of the ulcer was quite accidental, perhaps depending in many cases on the position where the foreign body lay in contact with the mucous membrane. In cases of typhlitis which result from other causes than the presence of irritating foreign bodies, whether of inspissated mucus or fæces, or bodies more strictly foreign, such as fruit-seeds, the appendix itself is not so apt to be the seat of the disease as the walls of the cæcum, and the attack is apt to assume rather a different form.

* Dr. Woodward subsequently informed the Recorder that the tumor referred to is No. 6320, Surgical Section, Army Medical Museum. It was from the right cheek of a lady about 55 years old, and occupied the site of the parotid gland, which was apparently atrophied. It was excised November 10, 1873. Nos. 6459 to 6470, Microscopical Section, Army Medical Museum, are thin sections of this tumor, stained with carmine and mounted in Canada balsam.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

W. S. W. RUSCHENBERGER, M.D., in the chair.

WEDNESDAY EVENING, NOVEMBER 4, 1874.

DR. WILLIAM S. FORBES read a paper on "A New Operation for Certain Cases of Cleft Palate and Bifid Uvula."

The new operation is adapted to cases in which each half of the split uvula and velum is large and thick, and in which the cleft does not extend entirely through the velum up to the hard palate.

It consists in making an incision from a little below the middle of the right half of the uvula, on one side, and carrying the bistoury up to a point above the arch of the fissure, and then, turning the bistoury, to bring it down to a corresponding point in the uvula of the opposite side.

The column of flesh on either side of the fissure, now liberated by this incision, turns on its attached pedicle, or falls from the arch, leaving a long uvula with an oval opening in its base.

In the first case, a few days after the operation granulations sprang up, and the parts contracted. A day or two later, when the upper part of the wound began to widen, the tensor and levator palati muscles were divided with a double-edged knife, as recommended by Sir W. Fergusson, all tension being thus removed. The upper edges of the opening then approached the median line; and, under the application of a little nitrate of silver, cicatrization and narrowing of the entire opening rapidly ensued.

This case eventuated in a cure, as did also a second one in which a similar operative procedure was practised.

DR. JOHN ASHHURST read a report of a *fracture of the neck of the scapula* which occurred in a boy five years old, who had been struck by a falling door, in front of the right ear and on the right shoulder. When he saw the case, on the third day, there was a good deal of pain and tenderness, with moderate swelling, but very little deformity. Careful examination showed that there was no fracture of either the humerus or the clavicle, nor of either the acromion or the coracoid process; but the latter appeared to move with the head of the humerus, and, by grasping the neck of the scapula between the fingers laid upon the shoulder and the thumb thrust firmly into the axilla, deep-seated crepitus was elicited upon the arm being forcibly rotated. The treatment consisted in maintaining the arm in the "Velpeau position" by means of broad adhesive strips and a bandage, and a satisfactory cure was effected in the course of four weeks.

GLEANINGS FROM OUR EXCHANGES.

THE STATE OF THE PUPIL IN CHLOROFORM-ANÆSTHESIA AS AN INDICATION OF DANGER (*Atlanta Medical and Surgical Journal*, November, 1874).—M. Budin, interne of the hospitals, in examining with care all the details of chloroformization, with the end of discovering some sign which may guide the surgeon in its administration, has observed that there exists a certain relation between the state of the pupils and the more or less profound anæsthesia of the subject. . . .

1. There exists in the surgical anæsthesia produced by chloroform a constant relation between the state of the pupil and the period of anæsthesia.

2. During the period of excitation the pupil is dilated.

3. This period passed, the pupil contracts; its atresia,

very marked for several minutes, accompanies, in general, complete anæsthesia.

4. Dilatation of the pupil supervening during an operation indicates in general that anæsthesia is less profound, and that return to sensation is near.

5. The state of the pupil may then serve as a guide in the administration of chloroform.

6. During operations of long duration, if the patient is to be kept completely insensible and immobile, the pupils must be kept constantly contracted.

7. Finally, efforts at vomiting may produce dilatation of the pupils, dissipate the insensibility, and awaken the patient; they annihilate in part the effects of anæsthesia.—*Progrès Médical—Gazette des Hôpitaux*, October 1, 1874.

FRACTURE OF THE STYLOID PROCESS OF THE ULNA (*Edinburgh Medical Journal*, November, 1874).—Mr. Neil Macleod reports the case of a man, æt. 32, who disabled his right hand in a fight, by a blow on his antagonist's face. He presented himself for treatment, complaining of pain near the wrist, and inability to use the hand. The fore-arm was between pronation and supination, and the disabled hand was supported on the other. On comparing with the other hand, there was no antero-posterior or lateral displacement, but there was slight ulnar flexion. On fixing *both* bones of the fore-arm, and moving the hand and wrist, no crepitus could be elicited. The same result followed fixation of the *radius alone*; but in fixing the *ulna alone*, a little above the styloid process, distinct crepitus was obtained on moving the hand and wrist antero-posteriorly. Further, no crepitus could be obtained by manipulation of the lower end of the ulna alone; but on fixing the wrist and lower end of the radius with one hand, with the other the distal end of the ulna could be pushed from its normal position forwards or backwards—more especially the latter.

Diagnosis.—Fracture of the styloid process of the ulna, and separation of the triangular cartilage.

INFECTION BY SYPHILITIC SEMEN (*New York Medical Journal*, November, 1874).—Dr. Isaac Smith, Jr., reports the following case, which he believes disproves the assertion of Professor Bumstead that it has never been proved that a female may, without becoming pregnant, contract syphilis through the semen of a syphilitic male, he having at the time no syphilitic lesion. A gentleman who had had chancre, secondary eruption, bubo, and engorgement and suppuration of the cervical glands, married after he had apparently been in good health for about twelve months. Soon after, his wife had prolapsus uteri, and a chancre was discovered upon the os. This was treated, and healed kindly. Six weeks later she had a specific fever, and as that subsided, a secondary eruption appeared, which soon yielded to treatment. Six months afterwards, the man had urethral chancre, while his wife was suffering at the same time from engorgement of the os uteri, with uterine leucorrhœa. They were relieved of these troubles, and since then have had perfect health. The woman has never been pregnant, and has never run past her time. The family is of the highest respectability.

EXTRA-UTERINE PREGNANCY (*The Boston Medical and Surgical Journal*, November 12, 1874).—Dr. E. W. Sawyer reports the case of a married woman, who had had five children, and in whom all the usual symptoms of pregnancy came on, and persisted until the third month, when colicky pains began to trouble her and continued throughout her gestation.

At the end of the ninth month regular labor-pains were developed, but subsided after two days. The head of the child could be felt high up in the pelvis; there

was no dilatation of the os uteri. Twelve days later, regular pains set in, and continued for a day, at the end of which all motion ceased, after a most violent action of the child. She then had slight hemorrhage for three months, but for some time afterwards her menses returned with the strictest regularity. It being decided to operate, an incision was made through the abdominal walls, and the cyst containing the child was removed. The patient did not rally, but died twenty hours after the operation.

MISCELLANY.

A NEW THERMOMETER.—A. Jaksch, of Kreibitz, Bohemia, proposes the use of glycerin thermometers, made as follows: An ounce bottle is two-thirds filled with glycerin of any desired color, and the bottle placed in a freezing-mixture of sal ammoniac, saltpetre, and water, so as to cool the liquid to 32° F. A glass tube twelve to fifteen inches long is passed through a good-fitting cork, so as to dip nearly an inch into the glycerin. The cork is inserted in the neck of the bottle and rendered air-tight with sealing-wax or a cement of varnish and chalk, and the thermometer is then ready to be graduated. On inserting the cork, the liquid rises in the tube a few inches.

The bottle is placed in melting ice, and the level of the liquid marked 32°, if the scale is to be Fahrenheit's. It is next placed in warm water, say at 132°, and this point marked. The space between these points is divided into one hundred equal parts, and this division carried down to the Fahrenheit zero, and upward to the top of the tube.

DECLINE OF HOMŒOPATHY ABROAD.—"It is not to be wondered at that we now obtain few open accessions to our ranks; that the vacancies occasioned by deaths are scarcely filled up by new converts. Apparently homœopathy is almost at a stand-still as regards professed adherents in this country. The 'Homœopathic Directory' of this year contains few new names of practitioners that were not in the 'Directory' of last year. Nor is it surprising that we have renegades. . . .

"The paucity of recent conversions to homœopathy in other countries of Europe has been admitted and commented on by the homœopathic periodicals, and is, I think, satisfactorily accounted for by what I have stated."—*Dr. Dudgeon's Presidential Address at the British Homœopathic Congress, June 4, 1874.*

VIOLATION OF THE PHARMACY LAW.—Three retail druggists were recently fined one hundred dollars and costs for violation of the act of Assembly which provides that no person shall carry on in this city the business of retailing drugs, chemicals, or poisons, or of putting up physicians' prescriptions, without first obtaining a certificate of competency from a Board known as the Pharmaceutical Examining Board, composed of competent druggists, and appointed by the Mayor.

It will surprise many members of the profession in this country to be told that elephantiasis græcorum exists in Canada. According to the *Toronto Globe*, there

cannot be any doubt but that in a part of the Dominion near the mouth of the Miramichi River there have been lepers for the last eighty or ninety years.—*The American Medical World.*

THE death is announced of Dr. Edward Smith, of London, well known to the profession by his papers on food, alcohol, phthisis, prison-diet, etc., etc.

NOTES AND QUERIES.

REMARKABLE CASE OF MEGACEPHALUS—RECOVERY.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—I was hastily summoned on the morning of the 27th to see Mr. J., æt. 40. He had been to a Thanksgiving dinner the day before, and to his club in the evening, and never felt better.

Symptoms.—Face flushed, headache intense, intellect obtuse, tongue furred and swollen, speech thick, skin hot and dry, odor frumentous and nicotic, pulse 90, temperature 102°, eyes looked so bad that I thought it best to send for the oculist, Dr. N. Found diplopia, muscæ, V $\frac{1}{8}$, media clear, no choking of disk, fundus normal.

R Pil. hydrarg., gr. x, at once;

Sp. mindereri, f3ss, q. h. s.

Evening.—Headache somewhat better, but worse in other respects; pulse 95, temperature 100°. Spasmodic jerking, slight delirium, much tremor. Consult with Dr. M. (nervous disease) at 9 P.M. No paralysis; sensibility normal; areas all right, as tested by the pricklers. Patient's vision had improved $\frac{2}{8}$; saw a joke: said he thought he was getting stuck.

R Galvanism, t. d.

Magnesii sulph., 3iss at a dose.

28th.—Much better. Pulse 75, temperature 98°. Bowels have been moved freely. Urine free, but cloudy. Sent a bottle of it to Dr. T. (renal specialist). Warm bath and chicken broth. Suspended galvanism.

29th.—Recovering rapidly. Discontinued treatment.

Met patient on Broadway not long after this; said he had got the bills, and looked very savage. Thought he was going to have another attack, and advised him to go to Europe. Said I had a young medical friend who would accompany him for expenses and a small consideration.

He said he thought I did not look very well myself, and told me to go somewhere—I don't know where the place is exactly, but remember thinking it was very hot, and how ignorant non-medical men are of climate and geography.

D. F. L.

NEW YORK, December, 1874.

At the Annual Meeting of the New York Society of Neurology and Electrology, held Dec. 21, the following officers were elected for the ensuing year: *President*, Meredith Clymer, M.D.; *Vice-President*, John C. Dalton, M.D.; *Councillors*, Austin Flint, Jr., M.D., D. B. St. John Roosa, M.D., Edward G. Loring, Jr., M.D., William H. Draper, M.D., William T. Lusk, M.D.; *Corresponding Secretary*, John J. Mason, M.D.; *Recording Secretary and Treasurer*, N. B. Emerson, M.D.; *Curator*, Edward G. Janeway, M.D.

Attest: ALFRED L. CARROLL, M.D., *Secretary.*

PHILADELPHIA COUNTY MEDICAL SOCIETY.

DR. D. Hayes Agnew, late President, will deliver the Annual Address before the Society, Wednesday, January 6, 1875, at 8 o'clock P.M., at the Hall of the College of Physicians.

The medical profession in Philadelphia are cordially invited.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM DECEMBER 22 TO DECEMBER 28, 1874, INCLUSIVE.

WINNE, C. K., ASSISTANT-SURGEON.—Assigned to duty at Sidney Barracks, Nebraska. S. O. 185, Department of the Platte, Dec. 17, 1874.

ABADIE, E. H., SURGEON.—Died at St. Louis, Missouri, December 22, 1874.

SATURDAY, JANUARY 9, 1875.

ORIGINAL COMMUNICATIONS.

A CASE OF INTRACRANIAL TUMOR, WITH MICROSCOPICAL EXAMINATION.

BY CHARLES S. BULL, M.D.,

Ophthalmic Surgeon to Charity Hospital, Assistant-Surgeon to the New York Eye Infirmary, Microscopist to the Manhattan Eye and Ear Hospital.

THE patient whose history will immediately follow was an inmate of the City Insane Asylum, under the care of Dr. A. E. Macdonald, Physician-in-Charge, and Dr. J. G. Kiernan, Assistant-Physician, to whose courtesy and kindness I am greatly indebted for the pathological specimen and the accompanying history. Unfortunately, the history is somewhat scanty, being deficient on some important points antedating his admission to the institution.

Anton B., 40 years of age, a native of Germany, became an inmate of the New York City Asylum for the Insane some time in February, 1874. We have no record of any premonitory symptoms, except a statement that the man's vision began to fail about six months previously. There is no history of any syphilis, but no information could be gained from the patient, as the history states that during Dr. Kiernan's service he did not speak. There is some doubt whether the patient had any vision when admitted to the asylum, but shortly after this he became completely amaurotic in both eyes. During his sojourn in the institution his hearing remained normal, and there was no disturbance in the sense of smell, which seems almost incredible when we come to consider the location of the tumor. There was no strabismus, no ptosis, and, in fact, no disturbance of function of any of the nerves supplying the eyeball and its appendages, except the branch of the motor oculi which is distributed to the sphincter of the iris. The pupils of both eyes were dilated and immovable when he entered the asylum, and remained so until just before his death, when they contracted. The variety of insanity under which he labored was melancholia, accompanied by delusions of a depressing character. There was no cataract in either eye, but, unfortunately, no ophthalmoscopic examination was made. At first sight there appeared to be no disturbance in the power of co-ordinate movements, as the patient could walk; but a closer examination showed that if he were allowed to remain in one position he soon fell over. At no time were there any symptoms of paralysis present. He was suddenly attacked by vertigo, five days before he died, and an examination of his urine showed traces of albumen. He died from pleuro-pneumonia and uræmia, though the coma was not strictly uræmic in character. At the autopsy, both cerebral lobes were found much softer than normal, the cerebellum seemed somewhat reduced in size, and the pons Varoli was found to be infiltrated with a structure of the same kind as the tumor. On lifting up the anterior lobes of the cerebrum, there was seen, in the median line of the skull, a tumor the size of a small orange, resting on the ethmoid and sphenoid bones, and rising, almost spherical, against the anterior lobes, compressing them against the vault of the skull, and producing a deep excavation in them. The tumor extended from the foramen cæcum of the frontal bone posteriorly as far as the posterior clinoid processes of the sphenoid bone, and laterally on

both sides over the greater wings of the sphenoid and orbital plates of the frontal. It measured two and five-eighths inches antero-posteriorly, two and three-fourths inches laterally, and two inches vertically. It was nearly spherical, though irregular and somewhat indistinctly lobulated, and at its base was firmly adherent to the dura mater over the ethmoid and sphenoid bones. It was covered with a delicate, highly-vascular membrane, probably a prolongation of the pia mater, and was of a grayish-pink color. The olfactory bulbs and nerves were completely flattened and very thin, the optic chiasm and nerves were flattened and pushed backwards, the pituitary fossa was filled up by the tumor, which on the left side also overhung somewhat the sphenoidal fissure. The third, fourth, the ophthalmic branch of the fifth, and the sixth nerves did not seem to have been encroached upon in their course, and yet the pupils were widely dilated, and so remained until just before death.

After the specimen, consisting of the base of the skull with the tumor in position, had been preserved in alcohol for three weeks, the eyes were enucleated and opened in the vertical meridian. The cornea and iris appeared normal, and the anterior chamber was of natural depth. The lens was in position, but presented a peculiar appearance; for while the posterior layers were cloudy, probably from the coagulating effects of the alcohol, the anterior layers were of a dense yellowish-white color, and much harder than the posterior layers. The vitreous was changed into a deep-yellow, grumous fluid; the retina was detached below from the ora serrata nearly to the optic nerve entrance, and very much thickened. The choroid appeared normal, as well as the optic nerve. There had evidently been a hyalitis with retinitis, which had caused some change in the lens, and the effects produced were about the same in the two eyes.

A microscopical examination of the optic nerves revealed the following state of affairs. The external sheath, continuous with the sclera, was enormously thickened, and the interspaces between the connective-tissue fibres were filled with round and fusiform cells, the result of inflammatory proliferation. The inner sheath was also hypertrophied, though not to the same extent, and here also the interspaces were occupied by round and fusiform cells. The fibrous skeleton framework of the nerve was very much thickened in all directions, at the expense of the nerve-fibres, which were compressed and atrophied. In some places the contents of the neurilemma had entirely disappeared, and the place was occupied by fat-globules and an amorphous detritus. In other places the spaces made vacant by the atrophy of the nerve-tissue were filled by the products of inflammation, round and fusiform nucleated cells, and some fibres. The central artery and vein of the retina were almost obliterated, from an encroachment on their calibre by the increase of fibrous tissue. Examination of a transverse section of the nerve corroborated what was found in a longitudinal section, and here the hypertrophy of the fibrous tissue of the nerve was particularly well shown. The same state of affairs existed in the nerve as far back as the optic foramen. The rest of the nerves, as far back as the chiasm, and the chiasm itself, were not examined, in order to avoid disturbing the tumor.

An examination of the retina showed that the thickness of this coat was due mainly to a great increase in the external granule layer, next the rods and cones. The nerve-fibre and ganglion-layers were scarcely altered, and the layer of rods and cones had undergone but little change. The connective-tissue framework or Müller's fibres stood out plainly, and the membrana limitans externa was very distinctly marked. The

external granule layer, however, was thickened, especially near the optic nerve entrance, where it was increased enormously and seemed to run into and swallow up the middle and internal granule layers, so as to form one mass of fine granules and round nucleated cells, pressed closely together and bulging forward towards the vitreous humor. The entrance of the optic nerve was but a trifle swollen towards the edges, and this appeared to be due to the hypertrophy of the retina, for it was somewhat deeply excavated at the centre. The nerve-fibres were atrophied by pressure, though not so much so as they were farther back. The *membrana limitans interna* was only faintly defined, but this might be due to post-mortem changes.

The choroid was apparently normal in texture, though there might have been a slight atrophy of the pigment-cells in its stroma; but there were no signs of any inflammatory process. The vitreous was very much altered. The mass of it was made up of inflammatory exudation, consisting of some fibres, and many round and oval nucleated cells with granular contents, some of the size of pus-corpuscles, others somewhat larger. Some of the oval cells had two nuclei with nucleoli, others only one.

The lens presented the usual appearance of a cataractous lens, the process being most marked in the anterior layers. Here the whole thickness of the anterior layers was filled with round and oval cells, with a very few altered lens-fibres running through them. The centre of the lens was comparatively free from the inflammatory changes, but the posterior layers were again very much altered, like the anterior layers. The posterior capsule was somewhat thickened, though not markedly so, and was firmly adherent to the hyaloid membrane. The cornea and iris were healthy, as was also the ciliary body. There had evidently been set up a pure neuritis by the pressure of the tumor upon the chiasm and nerves. The inflammatory action had commenced in the sheath, and from thence had spread to the connective-tissue frame-work of the nerves, causing an increase in the fibrous tissue, great proliferation of cells, and secondary atrophy of the nerve-fibres from pressure.

We have been accustomed to connect the presence of a cerebral tumor with a condition of ischæmia of the optic disk, or, as it is called, congestion-papilla, caused by increase of the intra-cranial pressure, and a secondary obstruction to the return or venous circulation of the eye. This produces enormous swelling of the optic disk, with serous exudation, and sometimes hemorrhages into the papilla and retina; and, secondarily, atrophy of the nerve-fibres if the pressure is not relieved. Now, whether this had occurred in our case as one of the first symptoms of the disease, it is now impossible to say; but certainly there had been a most marked "neuritis interstitialis," which probably extended from the optic chiasm down to the lamina cribrosa, and had ended in atrophy of the nerve-fibres, and this condition of affairs might easily have been recognized with the ophthalmoscope if the lens had not been opaque.

Exactly how this interstitial neuritis commenced it is very difficult to say. There were no signs of any meningitis anywhere at the base of the brain, so that it is not at all likely that the inflammatory process began in the meninges. Of course we know that a tumor of such a size would act as a foreign body, and be likely, from its position, to light up a perineuritis or inflammation of the sheath of the optic nerve, which would then spread by continuity of tissue and vascular supply to the inner sheath and skeleton frame-work of the nerve. This is perhaps the most probable origin and course of the neuritis in this case. From the position of the tumor it is evident that it could not have exercised any *direct*

pressure upon the cavernous sinus or upon the ophthalmic vein, but a very great *indirect* pressure undoubtedly existed through the medium of the circular sinus surrounding the pituitary gland, the anterior half of which must have been compressed by the growth, and thus, to a certain extent, the current of blood was forced back into the cavernous sinus. This would probably have produced congestion of the optic disks on both sides, with serous exudation, from hindrance to the return circulation through the central retinal vein as well as other veins emptying into the ophthalmic vein. The main process was, however, an inflammatory one—a simple neuritis descendens.

The tumor, on being cut into, appeared to the naked eye of a homogeneous structure, of a pale-gray color throughout, except at the centre, where it was of a light pink tinge. It seemed to be surrounded by a delicate vascular membrane, which was probably the pia mater or a prolongation of it. A closer examination showed the cut surface to be finely granular, but the tumor was firm and solid throughout. A microscopical examination showed that the growth was a sarcoma of mixed character, though the same general proportion and relations between its different constituents was preserved throughout. There was quite an extensively developed skeleton or frame-work, which was apparently composed of fibres of connective tissue, but a more careful examination proved that most of these apparent fibres were long, narrow, fusiform cells, with a large central nucleus and nucleolus, and granular contents which were placed end to end and side by side, and were arranged so closely as to resemble connective tissue. In addition to these cells in the frame-work, there were also some real connective-tissue fibres, which, running in every direction, served to strengthen the skeleton of the tumor. Taking the tumor as a whole, there were two kinds of cells which made up its mass: (1) small, round, nucleated cells, about the size of blood-globules, some being a trifle larger; and (2) long, fusiform, or spindle cells, with large nuclei; and hence the growth might be termed a round-cell sarcoma or spindle-cell sarcoma, according as one or the other variety of cell predominated. In many places the tumor assumed a carcinomatous character, for these fusiform cells or fibres formed incomplete alveoli, by enclosing spaces between them, which were filled by masses of the round cells and by larger round or ovoid cells, with immense nuclei, and sometimes two or three of them, which resembled the giant-cells that are occasionally met with in sarcomatous tumors. This alveolar arrangement was not, however, sufficiently well marked to stamp the growth as carcinomatous. One characteristic of the tumor was a frequent arrangement of round cells into balls or clumps, which were surrounded by a membrane-like layer of spindle-cells, and which is well represented in a wood-cut on page 662 of Billroth's "*Allgemeine Chirurgische Pathologie*," fourth edition. Sometimes within this cell-wall of spindle-cells were three or four nuclei, or what looked like such, each with a nucleolus, while again in others would be seen two or more complete, large, round, nucleated cells, each within its own cell-wall of spindle-cells, and the whole surrounded by a common wall of the same fusiform cells. The alveolar arrangement above spoken of was of the same appearance as is represented in Fig. 123 on page 663 of Billroth's work just quoted, taken from an alveolar sarcoma of the tibia. The cells were about the size there represented, though they were crowded somewhat more closely together than is represented in the figure, but the alveolar arrangement was not nearly so well marked.

Where there are so many different forms represented in a growth, it is not always an easy matter to decide

exactly in what class of tumors to place a specimen. As we see in this case, the influence which the original locality or mother-tissue exerts upon the development of the tumor is exceedingly powerful. The dura mater is a fibrous membrane with one serous surface, composed of fibrous tissue, that is, long fibres of connective tissue, fusiform fibre-cells, with some round, nucleated cells. A morbid growth originating here will be made up of just such tissue,—that is, it will be a spindle-cell sarcoma, with large fusiform cells, or perhaps a "sarcoma fibro-cellulare," if there is a great preponderance of these fibre-cells. The tumor was not very vascular, and there seemed to be a greater development of vessels towards the periphery than elsewhere. We learn from Virchow that sarcomata of the dura mater occur most often on its cerebral or visceral surface, and very rarely on the parietal surface. They also are most frequently met with at the base of the brain, upon the sella turcica or petrous bone. Their main effect is pressure, as well upon the cranial nerves as upon the brain itself. In the latter they frequently cause deep excavations, though they very seldom are directly connected with it. The subjacent bones also frequently undergo absorption and atrophy from pressure.

Unfortunately, the history of our patient prior to his admission to the asylum is almost a blank, and it is, perhaps, equally unfortunate that an ophthalmoscopic examination was not made. Yet it is very likely that this would have been impossible, owing to the cloudy state of the lens. At some period in the course of the disease the blindness must have been partial, and if the field of vision had been tested it would undoubtedly have proved defective in the outer half; that is, the patient would not have seen with the inner or nasal half of each retina, and would have presented that rare form of hemiopia caused by some growth situated in front of the chiasm between the optic nerves and pressing upon the inner half of both nerves which supply the inner half of each retina. Of course, a tumor situated in such a locality, and exerting a bilateral pressure upon the inner portions of both nerves, would end by producing complete amaurosis of both eyes, not only by growing over both nerves but also by compressing the chiasm, and this without regard to the arrangement of the optic nerve-fibres in the chiasm.

The subject of intracranial tumors with intra-ocular manifestations has long been the classical ground of ophthalmoscopy, and a very large number of cases have been noted and examinations carefully made, with reference to the symptoms which may be diagnosticated; and yet, when we come to examine the published literature of the subject carefully, we confess, with a feeling of disappointment, that we are really unable to decide finally the actual value of this or that change in the optic nerve in helping us to diagnosticate the presence or absence of an intracranial growth. These encephalic tumors are by no means common, and when we do meet with them it is often impossible to observe them long enough in their course to make our observations of value. Nearly all the statistics and tabulated lists of such cases which we possess, from Ladame's monograph to Annuske's paper in the *Archiv für Ophthalmologie*, Bd. xix., are unsatisfactory, fragmentary, and hence of not much value, and the history of

the preceding case belongs to the same category. A mere statement of the condition of vision, even when it has been carefully tested, is of very little value unless it has been accompanied by a careful ophthalmoscopic examination, for it is well known that a patient's vision may be actually perfect or nearly so and yet he may have a well-developed neuritis in both eyes. There is very great need of more accuracy in recording the results of examination in these cases, and not only should the vision and visual field be carefully tested, but these examinations should be frequently repeated as long as the patient is under observation. Only by this careful attention to details can we make our statistics and reported histories of any practical value; and not until we have learned this lesson faithfully can we feel ourselves able to cope with the difficulties attendant upon the diagnosis of intracranial disorders by means of the ophthalmoscope. It is my own conviction, from the observation of cases of optic neuritis and congestion-papilla which have been under my care, and of those which I have been allowed to examine by the kindness of brother practitioners, that optic neuritis reveals to us nothing more definite than the presence of organic disease of some kind within the skull, and that its diagnostic value is the same whether vision is affected or not. There is no difference in the variety of optic neuritis, whether the tumor or inflammation causing it be in the cerebrum, cerebellum, or large ganglia at the base of the brain; whether the cause be syphilitic or not. And more than all, to my own mind, neuritis is of no value whatever in localizing the trouble, except so far as it proves it to be within the skull, or at least posterior to the eyeball. In searching the literature of intracranial tumors so far as it has come within my reach, I have been able to find only twenty-five cases in which the autopsy showed that the tumor was situated in the anterior fossæ of the skull, lying in front of or upon the optic chiasm. We learn from this that a tumor occurring in this locality is a comparatively rare specimen.

214 WEST FORTY-FOURTH STREET, NEW YORK, DEC. 5, 1874.

CLINICAL NOTES AND REFLECTIONS.

BY WILLIAM HUNT, M.D.

YOU have, Mr. Editor, asked me several times for some notes of hospital experience for the *Times*. The pulse, temperature, skin, tongue, etc., style of notation, useful and absolutely necessary as it is for precise observation, is to me very tiresome: so, if you accept anything, it will have to be in another form, which, if not so instructive, will, I hope, at least be interesting.

ESMARCH'S METHOD.

We have used this method of controlling hemorrhage a number of times in the hospital. I think that much more care is required in its use in chronic than in acute cases. In the former class the operation will proceed bloodlessly, perhaps, until the main vessels have been secured and the apparatus is being removed; then the (enormous, sometimes)

number of vessels that have been developed during the long-lasting disease begin to bleed, the veins, especially the superficial ones, cannot perform their return function in the stump so long as there is one turn of the elastic cord about the limb, confusion is produced by the mixture of arterial and venous blood, and the case proceeding so beautifully at first may end in the loss of more blood than by the old way. Recently we have had a thigh-case in which I have thought it would have been better, immediately upon securing the main vessel, to remove the bandage and tubing entirely, and then to control the rest of the arterial bleeding by digital pressure until the remaining vessels were tied, thus leaving all the venous channels free. I have had great satisfaction with the method in acute cases where the loss of blood had been very great through the accident, and it was desirable, or even absolutely necessary, not to lose any more. In one instance a man was almost exsanguine from hemorrhage resulting from a gun-shot wound of the wrist. Without the method I should have applied a tourniquet and treated for reaction, but with it I was enabled to amputate at once. It is an important point in these cases to cut squarely through the muscles and vessels, for then the latter are easily seen, and not buried at varying distances in the nearly inaccessible interspaces made by oblique incisions. The injunctions of Prof. Esmarch himself, supported by the experience of Drs. Keen, Mears, and others in this country, as to applying the apparatus too tightly, are, I am confident, very important, particularly as to the production of paralysis. The professor says he has had to prevent his own assistants from committing this error.

The danger of driving morbid material out of the limb towards the centre of the body, as pointed out by Mr. Erichsen, is a serious consideration, but we are in want of any single observation as yet, I think, proving this point. According to our experience, then, what would seem to be wanting is the avoidance of venous pressure during the latter stages of an operation, especially in chronic cases,—a matter that is so easily managed in the ordinary way, by a good assistant at the screw of the tourniquet or with the fingers. Another thing: I think we must not allow our fears at the loss of a little blood to govern us too strongly. I have elsewhere stated my reasons for believing that patients otherwise in full health, and who have not lost much or any blood already, are in no wise worse for the loss of a small quantity during an operation.

ARE THE KIDNEYS ACTIVE ELIMINATORS OF ETHER?

A young man, aged about 30, was brought into the hospital for a railroad crush of the fore-arm, requiring amputation above the elbow. He had been a drinking man, but there was nothing in his appearance to suggest excess in this way, nor was there any other external sign of disease. He was taken into the clinic-room, and etherization was begun. Fortunately, I had my fingers on his pulse, and suddenly felt it drop after but a few inhalations had been taken. The patient seemed to be sinking. Etherization was suspended at once, restoratives were

applied, and he was removed from the room. In the afternoon he had reacted, and another attempt was made to operate. We were now fully on guard as to the ether. After a very few whiffs, the pulse began to sink, and we were threatened with a repetition of the morning's experience. The ether was withdrawn, and the operation was performed without it by Dr. A. V. Meigs.

For a few days the patient did well as to his stump, and also in other respects; but he then grew gradually worse, became feverish and delirious; the stump ceased to heal, but did not contract as in pyæmia cases. An examination of the urine was unfortunately overlooked, as there was no dropsy, nor other symptom to call attention to it. The condition was not pyæmic, but it was attributed partly to the accident and partly to the habits of the patient, and was classed under the general head of Surgical Fever.

The unfavorable symptoms continued, and death occurred in about two weeks after the injury was received. The post-mortem showed the kidneys to be in a marked stage of fatty degeneration, so that their functions must have been very materially interfered with. What relation had the inability to take ether to do with this condition? May not conditions of this kind often explain the unpleasant and even fatal action of an anæsthetic?

The practical lesson is obvious. Before a serious operation, should there be the slightest reason to suspect hidden trouble, examine the organs and the secretions, and be on guard.

ETHER AT NIGHT.

Caution as to the use of this agent at night cannot be too frequently urged. The lights should always be *above* the operator and etherizer, and the neighborhood of a low grate or of an open stove should be carefully avoided. The vapor of ether is very heavy, and falls rapidly, as any one can test by pouring a little of the liquid into a saucer and watching it roll and fall over the sides. One of the most exciting and seriously threatening scenes that I have ever been engaged in happened in this way.

A man required amputation of the arm (which was crushed by an engine) high up. There was, fortunately, just room for the tourniquet. The residents of the hospital, together with Drs. Agnew and Herbert Norris, were assisting. The latter administered the ether from a large sponge, and placed the bottle on a chair at his side. I had just removed the dangling fragments of the limb, when an assistant brought a candle close to the stump, and almost directly under the sponge. Instantly we were in a blaze. Dr. Norris involuntarily started back, and, in doing so, knocked over the chair with the large ether-bottle, which broke! Its contents were quickly spread, and the whole ring of the amphitheatre was on fire. A nurse lifted the patient from the table and placed him on the floor. Fortunately, the tourniquet held. Others sprang into the side wards and seized blankets, coats, and anything at hand, and we soon stamped the fire out, but were all more or less singed. The walls of the amphitheatre bore evidence for a long time, in the

scorched wood and blistered paint, of the danger. The exposed parts of the patient were superficially burned, but he never knew what had happened. He was placed on the table, and the operation was finished. The thorough anæsthesia here was fortunate for all. Had the fire taken place earlier, terror and excitement from ether combined would have made the man uncontrollable, and a fearful panic might have occurred in the hospital. As it was, no alarm was spread beyond the room.

Night operations with ether should, therefore, only be those of absolute necessity, and with the cautions enjoined there need be no danger. Chloroform, not being inflammable, has a great advantage over ether in this respect; but, I confess, I am afraid of it.

MAGGOTS.

If you keep the maggot-fly away, the maggots won't come. She deposits her little white masses of living young with astonishing quickness, and they are ready to go about their work with almost equal celerity. It is, therefore, nearly impossible, sometimes, to keep them away. But what if they do come? They are fearfully disgusting, that is true; but, except when they get into the wrong places, they do no harm: nay, it is a question whether they don't do a certain amount of good by acting as scavengers. They consume only the dead matter. I have often seen a wound healing kindly under them as though under a living poultice,—a poultice of active properties, converting harmful dead material into live, harmless substance.

Now, I am no advocate of maggots: as I said, they are disgusting; but, if they do come, get rid of them quietly, and do not make so much fuss about them, and so favor the popular notion that the man is going to die because he is breeding worms.

(To be continued.)

OPERATION FOR THE CURE OF ELEPHANTIASIS OF THE SCROTUM.

BY J. G. KERR, M.D.,

Canton, China.

(Communicated in a letter to Prof. Gross.)

AS I have not seen, in the works on surgery within my reach, any mention of operation for this disease, I will give a short account of a case operated on in the Medical Missionary Society's Hospital. In the Medical Reports of the Foreign Customs Service of China, the operation is very fully described by Dr. Manson, of Amoy.

Elephantiasis is frequently seen in South China in various forms. I have seen it in almost all parts of the body. In the leg it is most frequent, sometimes in one, sometimes in both. Next in frequency, perhaps, it attacks the scrotum. I removed, a short time ago, from a boy nine years old, the prepuce and half the skin covering the organ, for elephantiasis. I have seen it attack the nose, the lips, the neck, and in one case the arm was the seat of the disease.

My patient was a native of Tsang-shing district,

about forty miles from Canton, aged 42 years, and a laborer by occupation.

The scrotum began to enlarge about seven years ago, and has continued to increase ever since.

The patient (June 20) was laid on a table, with his feet on stools and the knees supported by assistants. After giving chloroform, an incision was made an inch or more to the left of the median line, opposite the orifice of the prepuce, large enough to admit the hand. The testicle was searched for, isolated, then returned, and the wound stuffed with cotton. The same thing was done for the right testicle.

A knife, entering the orifice of the prepuce, opened the skin to the pubis, and the penis was entirely dissected from the covering, the mucous membrane of the prepuce being cut off close to the base of the corona.

Two semicircular flaps were then dissected up from the sides of the tumor opposite the upper part of the thighs. The incisions for these flaps joined, or nearly so, in the perineum, but the upper extremities were united by a horizontal transverse incision on the pubis. The incisions for the testicles were then extended upward to this transverse incision, and the spermatic cords dissected up to the same extent.

Having placed the testicles and penis on the abdomen, in the hands of an assistant, the tumor was dissected from its attachments and removed, care being taken not to wound the urethra. Arteries bleeding too freely were tied when divided. The weight of the tumor was eight and a half pounds.

The flaps were brought together in the median line, and the upper edges joined to the upper side of the transverse incision over the os pubis, making a complete covering for the testicles, with the lines of union in the shape of a T. The penis projected at the point of union of the two lines, and was left to cicatrize.

The case progressed favorably, and in three weeks the wound was almost entirely healed, but the cicatrization of the penis was not quite complete when the patient left the hospital, twenty-seven days after the operation.

HYPERTROPHY OF CORPORA CAVERNOSA.

BY J. G. KERR, M.D.,

Canton, China.

(Communicated in a letter to Prof. Gross.)

THE subject of this was a well-developed man, aged 33 years, a native of Nan-hai district, a cook, and married, but having no children. The enlargement of the penis began when he was six or seven years old. On his admission to the Medical Missionary Society's Hospital, the organ was about three and a half or four inches in diameter. The left side was larger than the right, and it projected beyond the corona of the glans. There was partial phimosis, but the skin of the penis and scrotum was healthy. The testicles were of the usual size, but somewhat soft, and there was slight varicocele.

There was no sexual desire, and no erections, and sexual connection was impossible.

In consultation with Dr. Scott, of Canton, on the 28th of July, it was determined to operate, although it was not evident what the exact nature of the disease was. On opening the prepuce, the glands were healthy, and an extension of the incision showed that the cavernous bodies were hypertrophied and condensed. A considerable portion was removed, and the cut surface showed the open mouths of the arteries and veins, not numerous, but the hemorrhage was troublesome, and was only controlled by bandaging the organ on a silver catheter. I was satisfied at the time of the operation that no good was done to the patient, and I was gratified when, with a little sloughing of the skin, he recovered in a month's time, with the organ two and a half inches in diameter and six inches in circumference.

I find in Gross's and Paget's works on Pathology no mention of any hypertrophy of the cavernous bodies; and my operation has amounted to little more than an exploration in the living subject of a rare disease.

While the scrotum was healthy, there was also enlargement of the perineum, but, as it was not operated upon, the nature of it is not known.

AN ANOMALOUS CASE.

BY J. E. GARRETSON, M.D.

THE following anomalous, if not unique, case would seem to go far in favor of the view of Solly and Dalrymple, that mollities ossium is an expression of the cancer-vice.

Some four years back, Major S., of Tennessee, a gentleman of robust constitution and in apparently the most vigorous health, was sent to me by his physician for consultation and advice, the case presenting at the time these features: The teeth of the left side, superior jaw, from the central incisor to the last molar, were found loose in mass, not individually, but as if all that portion of the bone containing the alveoli had separated from the adjacent hard parts, forming with the dental organs a common sequestrum. Preceding this condition there had been no exhibition of inflammatory phenomena, nor, at the time of interview, was there the slightest expression of vascular perversion.

Using the exploring-needle in the examination, I found no evidence of bone, either in the loosened portion or in the parts immediately adjacent. The operation consisted of an external and internal flap, thus liberating the exfoliation, which, when removed, was found to consist of a remarkably healthy-looking alveolar mass, made up apparently of cartilaginous tissue.

Close study of the case, made at the time, verified the absence of any of the ordinary constitutional diseases, such as syphilis, tuberculosis, scrofulosis, etc., to which osteomalacia is frequently attributed; neither was there evidence or knowledge of local injury or of defect on the part of the nervous relations.

In the healing of the wound made at the time, it was noticed that simple and immediate reunion occurred with the raw surfaces of the flaps, and that these adhered to the enveloped parts by a mechanical rather than a physiological attachment. The patient in five days was sufficiently recovered to be out on the streets, and in three weeks returned to his home.

One year later, the patient returned to Philadelphia for further advice. Absorption of the remaining portion of maxilla, together with the malar bone, had progressed in the interim to an extent which showed marked deformity by flattening of all that side of the face. Horseback-riding in the early morning, and salt-water bathing, conjoined with the phosphate tonics, were directed.

The continued history of the case is given in the accompanying letter, just received from the attending physician. The final result I shall look for with great interest, trusting that it may be more favorable than would seem to be warranted by the description of Dr. Scruggs:

"SWEETWATER, TENN., December 10, 1874.

"DR. GARRETSON:

"DEAR DOCTOR,—Your old patient, Major W. E. S., on whom you performed an operation some time ago, requests me to write you in reference to his condition and ask you to make such suggestions for his treatment as you might think proper. You will recollect that the upper jaw and cheek-bone on the left side were removed. Since his visit to you, the other side has absorbed almost as much, but there is a bony projection under the right eye, while there is none under the left. There seems now to be a fleshy growth or enlargement that occupies the place where the bones were, and this is causing the face to protrude and to appear much enlarged. The growth seems to infringe upon the region of the left eye so much that the organ is forced outward and upward, leaving its socket considerably. The right eye, however, being protected by the bones just under it, is not disturbed, and in consequence the enlargement is forced downwards and outwards on the right side more than on the left. There is very little pain about the face, but a feeling of tightness, which is increased when the parts are unprotected. There is some secretion from the nares, front and rear, causing occasional spitting and blowing of the nose. There is a fleshy teat appearing in the left nostril, and I think likely the entire enlargement of the face is due to a similar growth. The major's health otherwise is very good. He has lately been using iodide of potassium in comp. syr. of stillingia, also Fowler's solution. But I do not look for a reduction of the seeming fleshy enlargement from this treatment. There seems to be no fungous appearance about the growth.

"Advise me what further is to be done.

"Very truly, etc.,

"R. F. SCRUGGS, M.D.,

"Attending Physician."

A CASE OF PARESIS OF THE CILIARY MUSCLE FOLLOWING DIPHTHERIA.

BY F. D. CASTLE, M.D.

E. D., a lad of 15 years of age, presented himself in my office a short time ago, with the complaint that he had for the last two days experienced great difficulty in reading and writing, and was obliged to hold the book at a great distance in order to perceive

the letters at all, but even then could not see distinctly. He found, however, that the use of his father's spectacles restored his vision for near objects to its former degree of acuteness. He also informed me that he was convalescent from an attack of diphtheria.

The refraction of both eyes was found to be emmetropic, but convex glass No. 20 was needed in order to relieve the parietic ciliary muscle and enable the patient to read and write with comfort.

The circumstance that no other muscle or group of muscles were affected in a similar way is interesting. The soft palate was entirely free from paralytic disturbance. There was also no anæsthesia of the fauces.

The treatment consisted in the use of convex glasses No. 20, with quinine and iron internally. The parietic symptoms rapidly disappeared, so that weaker glasses could be used for reading, and even these were eventually dispensed with. The use of electricity, as recommended by Benedikt, was not found necessary in this case, as recovery took place rapidly under the above-mentioned treatment.

NOTES OF HOSPITAL PRACTICE.

BELLEVUE HOSPITAL, NEW YORK.

CLINICAL SERVICE OF FRANK HASTINGS HAMILTON, M.D.,

Prof. of Surgery at the Bellevue Hospital Medical College.

FRACTURE OF THE CLAVICLE.

HERE, gentlemen, is a green-stick fracture, occurring in a lad about twelve years of age. About one week since, he fell from a swing, striking upon his shoulder, and breaking the clavicle near its middle; but, as often happens with children, the fracture was not complete. It is called a green-stick fracture because it resembles the fracture which occurs in a green stick when it is bent. Some years since, I experimented upon the bones of chickens, and I found that sometimes the bone would break partly off and then immediately spring back to its natural form, and in other cases it would remain bent. In the latter case the digitations in the line of fracture prevented the reposition of the fragments; but in both cases a callus would soon form over the seat of fracture. In the case of this lad, the fragments have spontaneously resumed their position; but on the day following the accident his father noticed a small swelling upon the clavicle at the point of fracture, and this has continued to increase until now it is of the size and form of the half of a pullet's egg, oblong, smooth, without discoloration, and to the fingers it feels hard, like bone. There is no crepitus or motion, the fragments being already partially united.

You will notice that the fracture is at the middle of the bone. This is usually the case in examples of partial fracture of the clavicle occurring in children; while the complete fracture of adults occurs, usually, at the junction of the outer and middle thirds.

No treatment is required in this case, except that the arm should be confined to the side of the body, in order to insure quietude, and that he should not be handled roughly. In one case reported to me by Dr. Green, of Cortland County, a partial fracture was converted into a complete fracture, after several days, by a fall.

The next case is a typical complete fracture occurring in an adult. The patient has also a fracture of the inferior maxilla; but of this I will speak at another time.

The patient fell upon his right shoulder, breaking the right clavicle obliquely, at the junction of the outer and

middle thirds. The outer end of the inner fragment forms a marked projection under the skin, although it has been carefully dressed with the figure-of-8 bandage recommended by Prof. Moore of Rochester. The principle upon which this apparatus is applied is sound, but, like all other forms of apparatus hitherto employed for broken collar-bones, it fails to accomplish the desired end in a large majority of cases. The dressing will be continued, but the result will be the usual overlapping and deformity. If the patient were fat, the deformity might not be seen, but he being thin and muscular it will be very apparent.

FRACTURE OF THE FEMUR—TREATED BY PLASTER OF PARIS.

This man suffered a simple fracture of his femur six weeks ago. He was taken immediately to the Park Reception Hospital, and, under the influence of ether, with extension made by pulleys, the plaster-of-Paris bandage was applied from the ankle to the loins. About two weeks later he was brought to Bellevue, and placed in Dr. Hamilton's service. The gentlemen in charge at the Park Hospital have a large experience in the use of plaster, and the dressings were well applied, except that, in the opinion of Dr. Hamilton, the foot should have been included in the plaster bandage. The swelling of the limb had also subsided sufficiently to leave the dressings a little loose. It was decided, therefore, to reapply the dressings. In the presence of the class the plaster was removed, and, on careful measurement, the limb was found to be shortened half an inch. He was then etherized, and extension applied until, in the opinion of Dr. Hamilton and of the house surgeon, further extension would be unsafe. The plaster bandages were then applied by the house surgeon, from the toes to the loins.

(The patient was subsequently brought before the class, in order to see what had been the result of this treatment. The splint was removed in the presence of the class, and, on examination, the limb was found united, with a shortening of one inch. This measurement was confirmed by several persons. It was apparent, therefore, that the limb had lost half an inch in length since the apparatus was applied; or, if we suppose that the extension made while the patient was under ether had overcome the shortening entirely, then the limb had lost one inch.)

A boy about eight years of age, whose thigh had been broken near its middle, was then brought before the class. The fracture was simple. It had been dressed with plaster of Paris, enclosing the entire limb and pelvis. On removal of the splint, the limb was found to be united, with a slight bend and a shortening of half an inch. Dr. Hamilton remarked that the bend would eventually disappear, and that the shortening would cause no lameness; yet with his own double splint for children a better result was generally obtained.

The patient was brought before the class for the purpose more especially of overcoming the ankylosis at the knee-joint, caused by the confinement. He was accordingly placed under the influence of ether and the ankylosis was broken up.

TRANSLATIONS.

TREATMENT OF AMMONIACAL CYSTITIS BY BENZOIC ACID.—MM. Gosselin and A. Robin have shown in a previous memoir that human urine, when ammoniacal, is toxic in a high degree, and that it plays an important part in the production of those accidents which occasionally supervene upon operations in the genito-urinary passages.

From this idea to that of prevention is but a step, and it is this which MM. Gosselin and Robin endeavor to elucidate in the *Archives de Médecine*. Their conclusions are as follows:

As the ammoniacal condition enters to a certain extent into the production of those accidents which supervene upon operations on the urinary passages, it is very desirable that it should be controlled, prevented, or diminished. Benzoic acid, the gums containing it, and probably also other vegetable products (salicine, cinnamic acid, etc.), conduce to this result. The hippuric acid thus created acts in various ways: *a*, in forming a hippurate of ammonium, less toxic than the carbonate of ammonium; *b*, in retarding the decomposition of the urine, and consequently the production of carbonate of ammonium; *c*, in preventing the formation of insoluble phosphatic deposits, which are one cause of cystitis and may become the starting-point of vesical calculi.

The administration of benzoic acid is to be recommended in the case of patients suffering from ammoniacal purulent cystitis, and particularly in the case of those who have submitted to operations on the genito-urinary passages.—*L'Abeille Méd.*, November 23, 1874. X.

REGENERATION OF THE SPINAL CORD.—Drs. H. Eichorst and B. Naumann have operated upon fifty-two puppies a few days old, because these animals offer the advantage of resistance to traumatism, and because they could be nourished by the mother. Thirteen of these puppies succumbed.

The operation was invariably performed by mashing the cord by means of a fine glass rod, introduced with as little injury as possible to the membranes.

The following were the results obtained: *Second day*, congestion and inflammation of the meninges. The cord at the injured spot presented the appearance of a jelly, composed, as was shown by microscopic examination, of the detritus of nervous elements. Above and below, in both gray and white substance, there was acute congestion with dilatation of the vessels, the walls of which contained proliferating elements. Destruction of the nervous elements was about taking place, and the elements of the neuroglia were proliferating.

By the *sixth day* the modifications still go on to a considerable degree. The entire crushed mass is in a condition of fatty degeneration, and begins already to be absorbed. In the cord, properly so called, the alterations extend but little beyond the point of lesion. They are particularly characterized by general inflammation of the conjunctiva and extravasation of the lymphatic elements.

After the *second week*, the meninges, which are closely adherent to one another, are the seat of a very decided proliferative inflammation; but these authors have in no case observed any suppurative meningitis.

It is not until the end of the *third week* that the "jelly" resulting from the crushing of the cord has disappeared completely, and that the true work of regeneration, so to speak, is observed. This work begins in the centre of a great number of cellules of the neuroglia condensed in the two ends of the cord, and is continued to the inner surface of the pia mater, so that a large cavity remains in the centre of the cicatrix. The authors have not determined whether this reparative process begins first in the upper or in the lower segment. Little by little the space circumscribed by this process diminishes; finally, at the end of the sixth month, it is somewhat larger than the ordinary central canal of the cord.

Up to the fourth week the renewed portion only contains the elements of granulation; little by little from this time nervous tubules are observed to become produced in this locality; these become rapidly more and

more perfect. Even after the eighth month, however, the nervous fasciculi are much less numerous at the borders of the cicatrix.

Another interesting point is the following: all that MM. Eichorst and Naumann have observed leads them to believe that the posterior furrow constitutes a true lymphatic sinus, in which this fluid circulates from the cervical to the lumbar region.

It is probable, also, that the postero-lateral furrow represents a lymphatic sinus, which surrounds on either side the posterior roots.—*Gaz. Heb.*, December 1, 1874; from *Archiv für Ex. Path.* X.

MAY CHLOROFORM BE EMPLOYED IN THE PERPETRATION OF CRIMES?—A correspondent of the *Société d'Hygiène et de Médecine Légale*, having been interrogated as a judicial expert as to "whether the employment of narcotics in the liquid or gaseous state can produce an anæsthesia so profound that violation of the persons to whom it has been given may be perpetrated without awakening them," gave an affirmative answer.

M. Dolbeau, apropos to this judgment, made a series of researches, the results of which were laid before the society at a recent session. He limits the question to the employment of chloroform, and starts with the following proposition:

"Can chloroform in vapor be administered to a person who is sleeping naturally, to the production of anæsthesia, without awakening him?"

In M. Dolbeau's experiments the chloroform was given in the usual manner, on a cone held an inch or so above the nostrils, so as to enable a constant view of the countenance.

In the first series of experiments three patients out of four were awakened by the chloroform-inhalations; in the second series, four out of six; in the third, only three out of nine.

It is not without interest to observe the increasing proportion of subjects anæsthetized; the manual dexterity acquired by the experiments is not without influence upon the results obtained. Accordingly, as a result of his experiments, M. Dolbeau believes himself authorized to formulate the following conclusions:

Scientifically, it is difficult, but often possible, to cause insensibility by means of chloroform in persons who are sleeping a natural sleep. Certain precautions, the employment of a perfectly pure agent, and experience, are also conditions which favor the attempt at anæsthesia.

It is probable that certain subjects are absolutely refractory; that is to say, that it is impossible to anæsthetize them without taking every precaution. Others, on the contrary, particularly young children, submit easily to anæsthesia, without having been awakened by the irritation produced by the anæsthetic agent in the air-passages.

From a criminal point of view, it is certain that chloroform administered to sleeping individuals may facilitate the perpetration of certain crimes: it is, however, probable that the conditions favorable to anæsthesia are rarely found on the occasion of criminal attempts. In justice, the expert should declare that it is possible, but not easy, to render a person who sleeps so insensible by chloroform that the said person might become the victim of any violence.—*La Tribune Médicale*, No. 323, 1874. X.

BILATERAL MASTODYNIA WITH SECRETION OF COLOSTRUM.—The following interesting case has been observed at the Heidelberg Clinic: The patient, a woman 26 years of age, pregnant only once, three years previously, irregular menstruation, applied for admission. On examination she was found to be anæmic, rather thin, no hysterical symptoms. The heart and lungs were normal. The mammae, pendulous and somewhat

flat, were normal in conformation; palpation of these organs gave rise to no abnormal sensation; there were no painful nodosities. While pressure exercised upon the mammae caused no pain, yet, on observation, some drops of a yellowish-white liquid were seen to exude from their orifices. This fluid, upon microscopic examination, showed the same appearance as colostrum.

The principal symptom of which the patient complained was pain, which had persisted for seven months previous to her admission to the hospital and continued during the nine months of her residence there. This pain, limited at first to the right breast, extended later to the left, and radiated in different directions, chiefly towards the shoulder on the right side. No tumor could be discovered in the mammary gland which would account for the pain, and this was therefore concluded to be due to neuralgia. No signs of pregnancy. Moderate leucorrhœal discharge.

Schultze, who reports this case, alludes to the various statements made by different authors as to its frequency. In looking over the literature of the subject, many cases of galactorrhœa may be found in both women and men, but this abnormal secretion has never been stated as co-existent with permanent pain. Nélaton alone has described a case of painful hypertrophy of the mammary gland in a young man of 26. (*Gaz. des Hôp.*, 1856, p. 126.) In this case the hypertrophied right mammary gland was the seat of violent pain, and, when compressed, gave exit to a liquid possessing the aspect and characters of milk. Schultze believes the galactorrhœa observed in these cases to be due to the same cause as the lachrymation observed in neuralgia of the trigeminae, and the nasal secretion caused by neuralgia of the second pair of cervical nerves.—*Gaz. Méd. de Paris*; from *Berlin. Klin. Wochenschrift*, No. 42, 1874.

THERAPEUTIC NOTES.

SYRUPUS ASARI CANADENSIS COMP. (Compound Syrup of Canada Snakeroot).—Take of

Canada snake-root, one troyounce;
Alcohol, three fluidounces;
Water, six fluidounces.

Mix, and digest for twelve hours, strain, pack the root into a percolator, pour the tincture upon it, return the first portions that percolate to the instrument till it passes clear; pass sufficient water through the percolator to make the tincture measure nine fluidounces; add to the tincture one avoirdupois pound of sugar, and dissolve without heat. To this add

Powdered cochineal, ten grains;
Carbonate of potassium, twenty grains;
Wine of ipecac, four fluidrachms.

Mix thoroughly; strain.

In reply to numerous letters of inquiry respecting the compound syrup of asarum mentioned by Dr. S. S. Bond in his article on the treatment of "Ascaris Oxyuris," page 818, *Phila. Med. Times*, Sept. 26, 1874, I send the formula for publication, disclaiming any intention to have it appear as original with me. This preparation has been in use in this city for twelve or fifteen years as a remedy in whooping-cough, and the above formula is copied from page 21 of "Non-Official Formulæ in Local Use, compiled and published by the Joint Committee of the Medical and Pharmaceutical Associations of the District of Columbia, Washington, 1867."

The discovery of the anthelmintic properties of this syrup was quite accidental. About three years ago the daughter of Mr. F., then four years old, was attacked

with vaginitis and pruritus, which was found to be due to migration of ascarides to the vagina. He prescribed the usual remedies, bitter injections, etc., with considerable relief, but the symptoms would return in about a week after treatment was discontinued. The child had suffered more or less for over a year, when Professor Johnson Eliot, M.D., was called on to prescribe for whooping-cough, and ordered the comp. syrup. asari in teaspoonful doses three or four times daily. A few days afterwards the child passed seat-worms in large quantities, either alone or agglutinated together into balls as large as a hazel-nut. The father consulted me as to the probable cause of their sudden destruction. Remembering that I had heard anthelmintic properties ascribed to the European asarum, I was led to suppose that our plant might possess similar properties, and commenced a series of experiments on such persons as applied in my store "for something for pin-worms," with such flattering results that I requested my medical friends to experiment also. Drs. Bond and Duncan seem to be the only ones who have experimented to any extent; and both with excellent success. Dr. Bond's article you have published; I will give Dr. Duncan's experience in a few words. He had but one patient, a little girl who suffered from vaginitis due to migration. He used the syr. asari comp. internally, and a decoction of asarum as injections to both vagina and rectum, and in two days all trouble ceased. This was six months ago; there has been no return of symptoms since.

My own method of administering the medicine differs somewhat from the others. I mix equal parts of comp. syr. asarum and fld. ext. senna, and order a dessert-spoonful for a child, or a tablespoonful for an adult, to be taken four times daily, and at bedtime a suppository consisting of one or two drops of oleoresin of asarum* with cacao butter q. s. Three or four days' treatment usually effects a cure. I furnish the above facts that the value of the medicine may be more fully tested by the profession in general.

DR. J. SCHAFFIRT, *Pharmacist*.

INEBRIATION (*New York Medical Journal*, October, 1874).—Dr. T. D. Crothers, after considering the physiological and pathological effects of alcohol, arrives at the following conclusions:

1. Alcohol diminishes and destroys nerve-force, tending to develop paralysis of motor and functional activity.

2. Inebriety is a disease of certain parts of the brain, and of the nutritive functions which it controls.

3. This disease is provoked by alcohol in variable quantity, depending upon some unknown condition of the body at the time of exposure.

4. A weakened will-power, and mental aberration, and tendency to inebriety, not inherited, are manifestations of disturbance of the co-ordinating power of the nutritive function.

5. This disease is inherited, and exists as an alcoholic diathesis, which may spring into activity, remain latent, or develop into other irregularities and functional diseases.

6. Inebriety is the active cause of many of the nervous and functional diseases of the brain.

* The oleoresin asari is prepared by exhausting powdered asarum with sulphuric ether, and evaporating spontaneously.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JANUARY 9, 1875.

EDITORIAL.

PERSECUTION OF VIVISECTORS.

AT the last meeting of the British Medical Association, M. Magnan demonstrated before a committee of the Association and various other gentlemen the differences in the action of alcohol and absinthe; tying, for the purpose, two dogs upon the table, placing a canula into the femoral vein of each, and injecting the poison. A very lively disturbance occurred during the experiment. Many protested against its performance, on the ground of its being cruel and unnecessary. One "British sportsman" was especially demonstrative, rushing forward and cutting the cords which bound the victims. Finally, however, the majority decided that the experiment should go on, and it was concluded. The press took up the affair very warmly, and at last the Royal Society for the Protection of Animals instituted a prosecution against Dr. Magnan and various Norwich physicians. The trial recently commenced amidst great excitement, but ended as a first-class farce. M. Magnan, preferring French despotism to English liberty, very naturally did not leave Paris in order to put in an appearance, and the prosecution failed entirely to prove that any other of the defendants were responsible for the experiment.

The legal persecution of vivisectionists has, we believe, never yet succeeded, and we trust it never may. At the same time, we think merely illustrative vivisection is often of doubtful morality.

A VERY extraordinary instance of the Philadelphia prejudice against specialism, founded probably on its being a *new* (?) thing, is seen in the recent action of the Managers of the Episcopal Hospital, a Board largely governed in such matters by its medical members.

The dispensary staff requested that special afternoon clinics be allowed, in order to relieve the general morning clinics, asserting that the latter were so overcrowded that it was impossible to attend properly to the patients. The staff demonstrated their statements by figures, but the Board of Managers declined to allow special clinics. Probably in the course of two or three generations Philadelphia conservatism will come to look upon specialism as allowable.

WE print under the head of "Notes and Queries," on account of the crowded state of our correspondence column, Dr. Richardson's reply to the recent animadversions on his paper. We are exceedingly sorry at the tone of the controversy, because the point at issue is one of great scientific importance. Dr. J. G. Hunt believes that the one-fiftieth objectives have no advantage over lower powers—Dr. Richardson believes that they have. Every microscopist is interested in the decision of this question, and we would suggest that a trial before competent judges should be had,—Dr. Hunt using his one-tenth, and Dr. Richardson his one-fiftieth. A result of real scientific value might thus be reached.

HYDROPHOBIA.—Mr. E. M. Wrench, F.R.C.S., in a letter to the London *Lancet* (December 12), states that he has known hydrophobia produced in man by the bite of a rabid jackal, and also states that although his own dog, having been bitten by a rabid animal, was killed before any signs of madness appeared, yet a puppy whose freshly-cropped ears had been licked by it was shortly afterwards seized with rabies, without other known cause.

SEVENTY thousand pounds sterling have been raised in Scotland for the purpose of improving the buildings of the Edinburgh University. But the sum not being sufficient, an effort is being made, with a fair prospect of success, to raise thirty thousand more in London.

THE odorless method of emptying cess-pools is now at work in Boston, to the great satisfaction of all parties concerned. How long shall that abomination—the night-cart—slop along our streets at the hour when places of amusement are dismissing and parties breaking up?

CORRESPONDENCE.

PHYSIOLOGICAL INSTITUTE OF LEIPSIK.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

THE rapidity with which my short account of Ludwig's jubilæum was put into print was the cause of some pleasure, and perhaps a little astonishment, on this side of the Atlantic, as it decidedly antedated any similar account published here or in America either. I ought, however, to say that the jubilæum took place on the 15th of October, while I find in the *Times* that it is dated the 14th; whether that be the fault of your devil or my dinner I cannot decide, but I think of the former.

As soon as heads were clear after the festivities, the Physiological Institute began work actively and in all its branches. These consist of a Histological, Physical, and Chemical Section, each of which occupies its own part of the building, which itself is worthy of a description.

It is a two-story U-shaped structure, with a basement. The upper floor is occupied by the family of Professor Ludwig; and in the basement, where the janitor lives, are to be found an ice-room, a home for frogs, an engine, which supplies power to the floor above, a workshop well supplied with tools, which the janitor, himself a carpenter by trade, superintends when occasion requires, a nicely-warmed room for animals with biliary and other fistulæ, and then the necessary rooms for the storage of coal and chemicals, as well as one for the safer carrying out of more dangerous chemical processes.

Under the lecture-room, which is a one-story addition which springs from the bottom of the U and extends between and parallel to its two limbs, is a menagerie for dogs, where they are exceedingly well housed and fed. These, however, are the only four-footed creatures kept in the building itself.

On the floor above, one wing is occupied by the chemical laboratory, out of which open at one end a room for spectroscopic work, and a balance room. This is moderately well supplied with the necessary conveniences, and is presided over by Dr. Drechsel. In the main building, which is, however, no larger than the wings, are the rooms more especially devoted to physical investigation, and where the animals are usually operated upon. In this, too, Professor Ludwig has his room, and there is a small library of the books and journals most likely to be needed by the students. The Microscopical or Histological Department comes next, and takes up the remaining wing, while, as I have said, in the space included by the three sides projects the lecture-room, which, though well supplied with conveniences for physiological demonstrations, is much too small for the class that crowds into it five times a week. Its small size and the absolute want of ventilation produce an atmosphere in the course of ten minutes to which that near the upper benches in the lecture-room in the old University building on a winter afternoon was as a breezy mountain-top; but in spite of that the lecturer always has an attentive and numerous audience, principally composed of medical students.

The students in the Institute nearly all, this year, come from other parts of Germany itself, but there are an Italian, a Russian, an Englishman, and two Americans. Last year, I am told, there were very few Germans comparatively. All the work done is of course under Professor Ludwig's general superintendence, but the Histological Department is under the more immediate superintendence of Dr. Flechsig, and on the Physical side Professor Kronecker is usually occupied.

The work that goes on is very various in kind, but there is a general tendency just now to the lymphatic system, which is being attacked from all quarters most vigorously, and I have no doubt that some good and interesting papers will be the result. Of course, of the exact line or nature of the work, even if I knew, I should not be at liberty to speak.

In the yard is a building in which rabbits and guinea-pigs are wonderfully well housed, and in which there are also two comfortable stalls for horses, with, in an adjoining room, a table and other arrangements for their dissection. It is but proper to state, before leaving this part of the subject, that, throughout, the animals are, whilst they live, most scrupulously attended to and fed and most kindly treated, while during the experiments everything possible is done to alleviate whatever suffering may necessarily be caused.

The Christmas vacation is rapidly approaching, and we are to have, I believe, nearly three weeks. This seems a long time to us, especially as in the spring there comes another of six weeks, and the summer vacation practically lasts from the 1st of August to the last week in October, while the students while at work—the medical students at least—are not driven as hard, in my opinion, as are ours at home.

These long vacations, however, are not intended so much for the benefit of the students as for that of the professors themselves, one of whom said the other day in conversation that while the student needed relaxation, and at the same time leisure to digest and assimilate the immense amount of fact and theory furnished him during the term, without this breathing-space the professors themselves, from whom something was of course always expected, would have no opportunity for original work, or at least very little. This would apply with even greater force in the latitude of Philadelphia, where the temperature of the summer months is not such as to invite prolonged mental effort.

As an offshoot from the Physiological Institute there exists a Physiological Society, composed principally of the officers and students of the former. It meets once a week, and as a rule a paper is read, of which the title has been announced beforehand. The reading of this is apt to be followed by an animated discussion, and, later, a fair proportion of the members adjourn to a neighboring restaurant, and bury in beer and supper whatever hatchets may have been disinterred earlier in the evening.

I read with much interest in the *Times* for November 21 the question of Dr. Macé, whether an International Medical Congress is to be held in Philadelphia in 1876,

for I have little doubt that if such a meeting were held, a number of eminent men from Europe would attend it. They would then have the opportunity of seeing something of America, in which many of them take great interest, and we at home could see and hear the men with whose writings we are so familiar. If, in addition, subjects for discussion were so chosen that men not exactly medical, but whose work has important bearing upon medicine and hygiene, could be induced to contribute papers and to attend, the meeting would be one of the greatest interest and importance.

LEIPSIK, Dec. 14, 1874.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—So much has already been written about the *climate of the Bermudas* by those whose statements are based upon an extended personal experience, that I have hesitated to add my opinion, founded as it is upon a short visit, to this much more valuable testimony. The appearance, however, of an article entitled "Bermuda as a Winter Resort for Invalids," in a late issue of the *Philadelphia Medical Times* (December 19, 1874), from the pen of one who seems to have even less practical knowledge of the Bermudas than myself, has removed this hesitation, and has afforded an opportunity of placing before the profession a few facts which bear upon the subject.

The Bermuda Islands form, as every one knows, a small archipelago situated in the Atlantic, in latitude $32^{\circ} 15' N.$, longitude $64^{\circ} 51' W.$, and nearly six hundred miles distant from Cape Hatteras, the nearest point of land. The archipelago consists of one hundred and fifty islets, which occupy the southeastern side of a long coral reef; they form an interrupted chain of land fifteen miles long, and five miles wide at its broadest part, and with its long diameter extending from northeast to southwest. The chief of the group is Bermuda, or the Great Bermuda Island; upon it is built the town of Hamilton, the seat of the Legislature.

The islands are of calcareous formation; their surface is very irregular, and, although there are no mountains, there are numerous rather high hills, some of which are barren, while others are well wooded and fertile. Owing to the porous nature of the soil, little or no water accumulates upon the surface, even during the heaviest rains, and the amount of low-lying or marsh land is very small. There are no springs upon any of the islands: the inhabitants are therefore obliged to collect rain-water for drinking and other purposes; but so much care is exercised in this process, and the number of cisterns is so great, that there is always an abundant supply of pure water.

The nature of the climate of the Bermudas is what might be expected from their isolated position: it is oceanic, that is, the atmosphere is moist, and there are no great variations in temperature; both of these characteristics are intensified by the warmth of the Gulf Stream, which heats the cold air passing over it from the southwest, and by so doing enables more moisture

to be taken up. The winds from the northwest, on the other hand, are drier and colder, but not cold enough to affect the uniformly semi-tropical temperature of the islands. The features of the different seasons, and the influence of the prevailing winds, the southwest and northwest, upon the temperature, are well described by T. L. Godet, M.D., for many years a resident of Bermuda, in a work published in 1860, from which the following extract is taken:

"The most agreeable season at Bermuda is the winter, or cold season, which lasts from November to March; the mean temperature being 60° . The prevailing winds are then from the westward; but if from the northwest, fine, hard weather, with a clear sky, accompanies them, the thermometer varying from 50° to 56° . This weather often terminates in a very fine, bright day, with a very slight wind and partial calms. Afterwards the wind invariably changes to the southwest, and the weather becomes hazy, damp, and attended with heavy rains and gales, the thermometer rising to 66° and 70° . These alternate northwesterly and southwesterly winds prevail during nine months of the year, the wind remaining at no other point for any length of time. Spring commences at the end of February, and the weather usually continues mild, with refreshing showers of rain and gentle breezes from the south and west, until the end of May.

"The summer begins in June, and the weather becomes hot. Calms about this time generally replace the gentle breezes of May; the atmosphere becomes sultry and oppressive, and long droughts are common, which are usually succeeded by severe thunder-storms. The weather in September changes in character, and again becomes mild and agreeable."

In an appendix to the same volume, the average range of the barometer and thermometer for four years is given thus:

	Barometer.	Thermometer.
Maximum,	30.480	85.85°
Minimum,	29.236	49.00°
Mean,	29.858	67.43°
Oscillation,	1.244	36.85°

From another source we find that the total rain-fall for the year 1860 amounted to 65.14 inches.

That the statements of Dr. Godet are still applicable, or, in other words, that there has been no marked change in the climate, as suggested by a quotation in the article already referred to, is proved by reference to the latest official meteorological report, that of 1872; in this we meet with the following figures:

Range of Barometer and Thermometer.

	Barometer.	Thermometer.
Maximum,	30.410	94.2°
Minimum,	29.500	44.0°
Mean,	29.941	70.3°
Oscillation,	.910	50.2°

Total rain-fall, 66.90.*

* The average annual rain-fall in Bermuda is about 55 inches; in Philadelphia, about 50 inches.

Number of days on which rain fell, 175.

Wind from southwest on 110 days; from west on 28 days; from northwest on 53 days, etc.

The annual mortality is nearly the same as that of Philadelphia, being about two per cent. of the total population. The colony has occasionally been visited by yellow fever, but since its settlement, a period of over two centuries, there have been only eight epidemics of this disease.

As my visit to Bermuda was made in the spring, I am unable to speak from experience of the winter weather, but that of May (1874) was as pleasant as a warm sun, a clear sky, and delightful sea-breezes could make it, and was thoroughly appreciated after exposure to the damp and chilly days of April in Philadelphia.

From a somewhat minute inquiry made at the time, I was led to believe that November, December, March, and April were even more pleasant than May, the air being more bracing, and better adapted to out-door exercise. In January and February, periods of dampness and rain are liable to occur; though there are many days during these months which will bear comparison with our finest October weather. On the other hand, June, July, and August are too warm to suit those who have been in the habit of seeking a cool climate at this season of the year. Now, although the climate of Bermuda may be agreeable to the tourist during the early winter and spring, when a great part of the pleasure consists in escaping from the slush and monotony of our large cities, it does not necessarily follow that it is a proper one for all classes of invalids. I think that patients affected with phthisis, for instance, need a drier and more bracing atmosphere, and that those localities in which these conditions exist should have the preference over Bermuda, although in cases which are not too far advanced, and in which a great desideratum in a change of residence is to increase the facility for an out-door life, it seems that, during the proper season, these islands are quite as suitable as other more southern and more tropical places of resort.

Upon this subject Dr. Godet remarks,—

"As far as the author's observation goes, the effect of residence in Bermuda on such persons [those of "general delicacy of constitution"] is usually beneficial, especially on those who are predisposed to scrofula or pulmonary consumption, or who have evinced a peculiar tendency to colds and bronchial affections during the winter months."

Whether the climate is adapted to consumptives or not, there can be no doubt that there are many conditions to which it is suited. I refer to the various bronchial, rheumatic, and neuralgic affections, to general debility due to over-work, and to those cases in which complete convalescence after acute illness is delayed during our long, cold spring. I fully agree, however, with the correspondent of the *New York Post*, that Bermuda is no place to send "the dying," having always regarded it as good practice to keep persons in that condition at home. The invalid must not expect to find in this out-of-the-way part of the world the com-

forts of his own fireside, or even the accommodations of our large hotels, but he will be provided with a *clean* and plainly-furnished room, a *clean* bed, and an abundance of wholesome, well-cooked food. There are no open fireplaces in the sleeping-rooms; indeed, in the judgment of the inhabitants, they are unnecessary; but it is probable that as the wants of the travelling public become known, these, with other luxuries, will be introduced. This may be so even at present, for, since my visit, many alterations and additions have been made to the Hamilton House, the principal hotel.

Until recently, the great drawback to the Bermudas was their difficulty of access, not on account of the roughness or length of the voyage,—three days and a half being the usual time required to make the passage between New York and Bermuda or back,—but because of the poor accommodations for passengers on board of the steamers. The *Canima*, the only reliable one, was very deficient in this respect, but a thorough refitting at Cramp's ship-yard last fall has improved her wonderfully, and she is now quite comfortable. This vessel is seaworthy and fast, and since being refitted has, I am told, made several trips in the short space of sixty hours.

These few remarks may perhaps be enough both to show that no one need entertain the fear of either "starving" or "suffering for the ordinary comforts of life" in Bermuda, and also to induce those who may think the matter of sufficient importance to seek further information elsewhere.

LOUIS STARR, M.D.

REVIEWS AND BOOK NOTICES.

CYCLOPEDIA OF THE PRACTICE OF MEDICINE. Edited by Dr. H. VON ZIEMSEN. Vol. I.—Acute Infectious Diseases. Translated by various American Physicians. William Wood & Co., New York, 1874.

The coming of this work has been so loudly trumpeted that any account of its scope and aims is at present superfluous. This first volume contains about seven hundred neatly-printed pages of large, widely-leaded type, having just about sufficient matter to fill three hundred and fifty pages of the United States Dispensatory. We mention this because very many buyers of medical books judge whether a book is dear or cheap by the mere size of it. Judged by the size, the volume is a cheap book; judged by the amount of matter in it, it is a dear one.

As in all books of similar character, the articles are unequal, although none of them in the present volume are really poor. The first subject treated of is typhoid fever, which is handled in a masterly manner by Dr. Liebermeister, whose discussion of the use of the antipyretic treatment should be read by every one. We must, however, protest against the atrocious starvation diet which he recommends. He says, "*Water* is the *one nutritive* [?] substance which the patient needs most. . . . The fact is, mucilaginous barley-water, thin oat-meal gruel, and the like, combined with not very strong meat-broth, constitutes the most desirable diet. The patient may have, if he like, milk, but only when boiled and *reduced with water*." We should judge it to require a German constitution to withstand starva-

tion and typhoid fever at one time, even if an abundant supply of that highly nutritious and fattening food—water—was allowed both internally and externally. We fear very much that, throughout the whole *Cyclopedia*, the department of treatment will be very weak. Thus, in Dr. Heubner's article on dysentery, pathology, symptoms, etiology, etc., are all good, until the section on treatment is reached. We doubt if this will give as much useful knowledge as is contained in Hartshorne's *Essentials* upon the same subject. The value of calomel is not at all discussed. The ipecac treatment is not mentioned, beyond the statement that ipecac has been employed in the disease; and none of those little but very important details which a practitioner looks for in so pretentious a work are to be met with.

Prof. Lebert has four articles in the volume, upon Relapsing Fever, Bilious Typhoid, Typhus Fever, and Cholera, respectively. His "Bilious Typhoid" seems to be a mongrel disease, the illegitimate offspring of an amalgamation in the author's mind of epidemics of relapsing fever and of malarial bilious fever.

Dr. Haenisch, who writes the article upon yellow fever, is evidently better acquainted with the disease as it appears in literature than as it appears in nature: he has, however, seemingly seen two cases, which he records at some length.

We have not space to review the volume before us at length. The book which comes into natural competition with the *Cyclopedia* is Reynolds's *System*, and we do not hesitate to express the opinion that, so far as can be judged from a single volume, if the practitioner can buy only one of these works, the English should be his choice; not merely because it is a cheaper book, but because, in our belief, it is a better working book, containing much more information adapted for immediate clinical use. At the same time, it is right to say that the volume indicates that in the departments of pathology and etiology the *Cyclopedia* will be unrivalled, and will therefore be a necessity to any one desirous of thoroughly knowing the science of clinical medicine.

TRANSACTIONS OF THE MEDICAL SOCIETY OF NEW JERSEY, 1874.

In this volume, which contains a handsome portrait on steel of the late Dr. Cooper, of Camden, New Jersey, we notice a number of things of interest. Dr. Sharp, of Medford, details a case of puerperal convulsions treated very successfully by two hypodermic injections of three drops each of the saturated tincture of *veratrum viride*. Dr. S. G. Carpenter asserts, in a paper on tetanus, that he has seen twenty-six out of thirty-seven cases get well. Dr. Carpenter must be the champion tetanus doctor. We doubt if any other one man on the continent has seen thirty-seven cases of the disease. Dr. C. W. Lanson narrates a curious case of aconite-poisoning. Dr. J. B. Mattison claims that the deep injection of chloroform is of the utmost value in obstinate neuralgia, even in true tic *épileptiforme*; whilst various authors discuss the value of chloral, or report cases of tetanus, placenta *prævia*, excision of the hip, etc., etc. A good deal of this matter is of real interest. How much better if the State Transactions were confined to purely business matters, and what else is worth publishing transferred to the pages of a live journal, instead of being buried in a volume having no circulation outside of the State!

CONTRIBUTIONS TO THE ANNALS OF MEDICAL PROGRESS AND MEDICAL EDUCATION IN THE UNITED STATES BEFORE AND DURING THE WAR OF INDEPENDENCE. By JOSEPH M. TONER, M.D.

This brochure of 118 pages really belongs to the great class of local histories, and is largely composed of brief

biographical sketches. It contains very many interesting facts, whose gathering together must have been a very protracted and uninteresting labor. Indeed, the amount of human hopes and human actions summed up in its pages shows very forcibly the intrinsic littleness of the single individual man.

A HANDBOOK OF THERAPEUTICS. By SIDNEY RINGER, M.D. Fourth Edition. William Wood & Co.

The work of Dr. Ringer is so well known to the American public that we merely announce the appearance of a new edition. The chief change in the book is in the addition of articles upon Phosphorus, Croton Chloral, and Hamamelis.

CLINICAL LECTURES ON DISEASES OF THE URINARY ORGANS. By SIR HENRY THOMPSON. Second American, from the Third English Edition.

In announcing this new edition of a well-known book, it is only necessary to state that the whole subject has been brought down to 1873, and that two new lectures have been added.

GLEANINGS FROM OUR EXCHANGES.

DETERMINED SUICIDAL MELANCHOLIA (*Edinburgh Medical Journal*, November, 1874).—Dr. Joseph J. Brown reports the case of a physician, æt. 25, who was admitted to the Royal Edinburgh Asylum in consequence of intense suicidal melancholia. He had always been healthy, was a hard-working and successful man, and, with the exception of one cousin, there had never been any insanity in his family. After experiencing a severe disappointment, he began to complain of headache and sleeplessness, then had delusions that his soul was lost and that it was a crime for him to live any longer, and finally tried to poison himself by refusing food, and by taking belladonna. He was then sent to the asylum, and, at intervals of a few days, tried to kill himself by pushing his finger down his throat; by eating berries of *arbor vitæ*, which caused nausea and diarrhœa; by swallowing small stones to the number of eighty-two, weighing twenty-four ounces, which were all evacuated; by taking an overdose of whisky, and afterwards some poison, whose character was undiscovered, but which produced coma, intense depression, general tremors and convulsions, and required the most energetic stimulation to counteract. A few days later, while an attendant was painting *liquor gutta-perchæ* over an excoriation upon the patient's sacrum, he snatched the bottle, and swallowed, as nearly as could be ascertained, about two ounces of the mixture. He soon became comatose, respiration ceased, the radial pulse grew scarcely perceptible, and nearly all evidences of sensibility disappeared. The pupils contracted, and were insensible to light. The face was flushed, the conjunctivæ injected, and the muscles flaccid. Artificial respiration was at once resorted to, and the stomach was thoroughly washed out with tepid water. Hot bottles were applied to the feet, warm blankets to the body, and an enema of strong coffee with brandy was administered. Cold water was dashed in the face, and the galvanic battery was employed, artificial respiration being kept up continuously. Total suspension of the respiration existed for two hours and three-quarters, and profound coma for nearly twelve hours, during which time he experienced several relapses, ceasing to breathe, and becoming greatly cyanosed. At these times ecchymoses appeared on various parts of the surface. Enemata of hot beef-tea, beef-tea and brandy injected into the stomach through a tube, galvanism, and artificial respiration were the chief means em-

ployed to relieve him, and were finally successful. The heart throughout the whole remained steady and regular in its pulsations, though it was diminished in force. It was observed that when the stimulation by the battery was too long continued or too energetically applied, the patient grew more comatose afterwards, so that intermissions of ten minutes or more were rendered necessary.

ANOSMIA (*The Lancet*, October 31, 1874).—Dr. Hughlings Jackson is convinced that loss of smell is a symptom which does not receive the degree of attention it deserves. We are rarely consulted for anosmia, since loss of smell is not so important a defect as loss of sight or of hearing is. But anosmia is just as *significant a symptom* as amaurosis is, and if the patient who is anosmic has also severe and continued pain in his head, and urgent vomiting, the symptom thus qualified would point to local coarse disease—*e.g.*, tumor, syphiloma, etc.—inside the head, quite as strongly as amaurosis (from optic neuritis) in the same association would do. Another thing to be considered is, that just as optic neuritis may exist when the patient supposes his sight to be quite good, so the presumption is that olfactory neuritis may exist when the power of smell is not obviously diminished. Again, it must not be concluded that anosmia depends on disease actually involving or pressing on the olfactory bulbs, any more than we must conclude that amaurosis from optic neuritis depends on disease involving the optic nerves, optic tracts, or corpora quadrigemina.

So-called "subjective" sensations of smell are occasionally warnings of epileptoid seizures; they are rarer than subjective "auras" of vision, but commoner than auditory auras. They occur in cases where the patient has no smell in the ordinary sense of the expression. They are presumably analogous to the colored vision of amaurotic patients, for patients who are blind are not always in darkness; they are, for example, sometimes in "redness."

KOUMISS (*Chicago Medical Journal*, November, 1874).—Dr. De Wolf, in an interesting article on the subject of koumiss, or fermented mares' milk, refers to its mode of preparation by the Tartars, who, in order to obtain the milk in sufficient quantity, are accustomed to separate the foal from the mare during the day, allowing it to suck only at night. The mare's milk is kept in a bag made of horse's hide undressed, which by smoking acquires a degree of hardness. Its shape is conical, somewhat triangular, from being composed of three different pieces set in a circular base of the same material. The sutures, which are made with tendon, are secured by a covering on the outside with a doubling of the same skin closely fastened. These bags are used both for the preparation and transportation of koumiss, and have a dirty appearance and disagreeable smell.

There is no doubt that koumiss has great therapeutic value, and the legitimate and rational indications for its use are apparent to the practical physician. It cannot be as specific in phthisis, but it may be of immense service in counteracting the disturbed and degraded nutritive changes which predispose to it, while it certainly supplies a food peculiarly adapted to conditions of exhausted vitality, emaciation from any cause, and the gastro-intestinal affections of children. In brief, it must be accorded a high place in the series of plastic nourishments.

The quantity of koumiss advisable to take in commencing its use should not exceed one champagne bottle daily for an adult, and even that amount sometimes produces a slight febrile reaction. If headache occurs, it should be suspended for a day or two; but in a short time a toleration is generally established, and the patient soon discovers how much he can take, and then he may live entirely upon koumiss, or, when the

stomach will tolerate other food, it may be added. It does not interfere with any other course of treatment. The secretion of urine is generally much increased. When a tendency to constipation exists, the fresh product should be used, but if diarrhoea is troublesome, an older sort should be taken. A piece of stale bread or cracker, eaten immediately after drinking, will relieve the fulness of stomach sometimes complained of.

The desire for sleep generally experienced after drinking koumiss should be regarded as beneficial, and should not be interfered with.

MISCELLANY.

THE AMERICAN MEDICAL ASSOCIATION.—"Our main objection is that the men who govern the Association and attend its meetings are far from fair representatives of the profession; that, consequently, the proceedings lack the dignity and discretion, and the papers, for the most part, the merit, that should characterize such a body. We cordially admit the former merits and services of the Association, as well as the high standing and character of its former leaders and supporters; but it has woefully degenerated."—*Boston Medical and Surgical Journal*.

DIAGNOSIS OF DEATH.—Dr. Monteverdi, of Cremona, has proposed a simple, easy, and certain method of seeing whether a person is really dead. He injects a drop or two of ammonia beneath the skin. If the person be dead, no effect, or next to none, is produced; but if the person be alive, a red color appears at the point of the injection. He has published a pamphlet on the subject, illustrated with six plates, and the plan, simple as it is, seems likely to be useful, to prevent the possibility of burying alive.

ACCLIMATIZATION OF IPECACUANHA IN INDIA.—The *Pharmaceutical Journal* notes that in the last report of Dr. King, Superintendent of the Calcutta Botanic Gardens, he states that the propagation of the ipecacuanha plant by root and leaf-cuttings has been so successful that there is at present a stock of 63,000 living plants; whereas, four years since there were at the Cinchona Gardens but twelve cuttings, of which seven were afterwards accidentally destroyed.

THE next Triennial Prize of £300, under the will of the late Sir Astley P. Cooper, Bart., will be awarded to the author of the best essay or treatise on "The Anatomy, Physiology, and Pathology of the Sympathetic Nervous System."

THE French Government is stated to have forbidden pilgrimages of the Algerian Mussulmans to Mecca, on account of the plague which prevails in some of the cities on the route, and the Egyptian authorities are stated also to have determined that no convoys of pilgrims shall leave Suez.

THE students at St. Petersburg are stated to be in rebellion against Prof. Cyon on account of the strictness of his examinations.

No less than 100,000 leeches are said to be required annually by the French military hospitals. The supply for the next three years has just been contracted for, at an average price of 125 to 135 francs per thousand.

THE PHILADELPHIA MEDICAL TIMES,—one of the ablest and most independent of medical journals.—*London Medical Record*.

NOTES AND QUERIES.

LENS-TESTING, NO. 2.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—Will you permit me to append a few explanatory notes to a letter in the *Times* of December 26, from your semi-anonymous contributor "J. G. H."?

This half-ashamed correspondent, whilst lurking behind these initials, inadvertently betrays himself by saying he is complimented in my paper of November 28, which, by the way, consists of unpretending "Notes on the performance" of two lenses, and claims to be no exhaustive report of their "testing." Since only one American's name beginning with H occurs in that article, I, of course, recognize my "friend" as J. Gibbons Hunt, M.D., advertised here and in New York as "Professor in the Woman's Medical College of Pennsylvania."

In the first place, allow me to explain that the possessive pronoun *my*, applied to the one-twenty-fifth and one-fiftieth, is so employed by Dr. Hunt and myself to avoid the inelegant repetition of proper names. Thus, Dr. H. says, "If my one-fiftieth resolves the Amphipleura,"* etc., meaning, of course, "If the one-fiftieth loaned to me by Mr. Charles Stodder resolves," etc., and not designing to dupe your readers into thinking he owns a high-power lens. Otherwise this statement would be, under the circumstances, a dishonorable wearing of borrowed plumes, or rather (since these lenses are "not achromatic"), a piratical sailing under false colors, which the learned "Professor" would indignantly scorn.

Respecting my trivial suggestion in reference to mounting podura scales, diatoms, etc., for testing high powers, I would remark that Dr. H., in his overflowing generosity and thankfulness, gives me quite too much praise. In reality, I made no more claim to being the first who proposed the use of mica than to precedence in employing very thin glasses "if they can be procured," and the only credit I deserve is on account of devising a plan for utilizing these materials, after Dr. Hunt gave them up in despair (vide *Medical Times*, loc[us] cit.).

Dr. Hunt's warm gratitude to me for teaching him how to focus a Bacterium, and how to prepare specimens for high powers, crops out so frequently in his essay, and so evidently springs from a very tender spot in the deepest recesses of pardonable vanity, that many strangers might underestimate his actual acquirements. To avert this injustice, permit me to assure you that in illuminating test-diatoms, or in staining and *celling* vegetables (such as his favorite and emblematic Nettle, my friend Dr. Hunt can probably equal if not surpass any microscopist in the Union; and whilst such prickly laurels adorn his brow, what need he care for his incapacity to define paltry Bacteria, or to produce any scientific papers which shall command that recognition from the medical "journals of this and other countries" to which he so feelingly alludes?

Dr. H.'s last paragraph of fervid eloquence charges me with telling almost the *naked truth*, or at least with coming as near that unclothed deity as poor human nature usually attains. But, Mr. Editor, my long (and much) tried friendship with Dr. Hunt enables me to declare that he did not intend to say anything of the kind, and that he never would have even seemed to make such an indecent accusation, had he not been blinded by his dazzling vision of the "immortal goddess," in all her unrobed majesty divine.

After all, is not the truth about which we have held this friendly discussion nearly as follows? The wonderful displays of lines and dots by Diatom students, interesting as they are, have about the same relative value to the real work of histologists and pathological anatomists which the delicate web of a spider has to the most useful products of our mills and looms; and the small, but positive, merit of my brief "notes" is that they give a faithful record of results obtained by an honest worker, *with*

"improved tools," in the peculiar province of the Arachnidæ (among whom my friend Dr. Hunt stands pre-eminent), and this without having spent a long and "useless" lifetime in the acquisition of their crafty tricks.

JOSEPH G. RICHARDSON.

3720 LOCUST STREET, PHILADELPHIA,
December 26, 1874.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—I am very glad that order has been evolved from chaos, and that we need no longer trouble ourselves about primordial elements and their relationships. Perhaps the Cincinnati Genesis needs confirmation: therefore I send you a gem printed in *Harper's Bazar*, which is too good to be lost. Please insert, that no links may be missing.

Yours, respectfully,
W. H. WINSLOW, M.D.

DARWINISM IN THE KITCHEN.

I was takin' oft my bonnet
One afternoon, at three,
When a hinseck jumped upon it
As proved to be a flea.

Then I takes it to the grate,
Between the bars to stick it;
But I hadn't long to wait
Ere it changed into a cricket.

Says I, "Surely my senses
Is a-gettin' in a fog!"
So to drown'd it I commences,
When it halts to a frog.

Here my heart begun to thump,
And no wonder I felt funky;
For the frog, with one big jump,
Leaped himself into a monkey.

Then I opened wide my eyes,
His features for to scan,
And observed, with great surprise,
That that monkey was a man.

But he vanished from my sight,
And I sunk upon the floor,
Jest as missus, with a light,
Come inside the kitching door.

Then beginnin' to abuse me,
She says, "Sarah, you've been drinkin'!"
I says, "No, mum, you'll excuse me,
But I've merely been a-thinkin'."

"But, as sure as I'm a cinder,
That party what you see
A-gettin' out o' winder,
Have developed from a flea."

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A CONVERSATIONAL meeting of the Society will be held at the Hall of the College of Physicians, Wednesday, January 13, 1875, at 8 o'clock P.M. Dr. William Goodell will read a paper on the "Management of Head-last Labors."

The medical profession in Philadelphia are cordially invited.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM DECEMBER 29, 1874, TO JANUARY 4, 1875, INCLUSIVE.

WHITE, R. H., ASSISTANT-SURGEON.—Relieved from duty in Department of the Gulf, and to rejoin his proper station in the Military Division of the Atlantic. S. O. 278, A. G. O., Dec. 30, 1874.

JACKSON, D., ASSISTANT-SURGEON.—Assigned to temporary duty at these Headquarters. S. O. 199, Department of Texas, Dec. 21, 1874.

SKINNER, J. O., ASSISTANT-SURGEON.—Relieved from duty at the Presidio, and to comply, without delay, with Par. 3, S. O. 260, A. G. O., November 30, 1874. S. O. 159, Department of California, December 22, 1874.

* Phila. Med. Times, vol. iv. p. 826 (report of remarks written out by Dr. H. himself, and MS. now in my possession).

SATURDAY, JANUARY 16, 1875.

ORIGINAL LECTURES.

ON THE PRINCIPLES WHICH GOVERN THE USE OF ELECTRICITY IN MOTOR PARALYSIS.

An Abstract of a Course of Three Lectures delivered at the University Hospital,

BY H. C. WOOD, JR., M.D.

LECTURE II.

IN my last lecture the laws of electrical science most important to the therapist were elucidated. To-day I shall consider the application of the force to the human body; and here, in the beginning, I shall assert, somewhat dogmatically, that in palsies the good effects obtained from galvanism are not due so much to the immediate action of the remedy as to the contractions of the muscles which it produces. It is true that some advantage is derived from the direct stimulation of the circulation in palsied limbs by the electricity, but the amount of this benefit is comparatively so slight that we may for the present disregard it.

Let us then, to-day, in the first place, determine, if possible, in what way muscular contractions are produced by electrical currents, and the best method of developing them in the healthy muscles.

When a moderately strong current of galvanism is passed along a certain length or portion of a nerve, there appear between the two poles two zones of disturbed nerve-function, separated by a neutral point at which the nerve retains its normal condition. In the neighborhood of the positive pole the irritability of the nerve, and also its power of transmitting impulses, are diminished, whilst in the proximity of the negative pole these nerve-attributes are increased: to the condition of diminished activity the name of *anaelectronous* has been applied, whilst that of increased activity has been called *kataelectronous*. Thus, in the accompanying diagram, *nn* equals the nerve; $+p$ and $-p$, the

positive and negative poles respectively; *np*, the point at which the function of the nerve remains normal, with the zone of anaelectronous on one side of it, and that of kataelectronous on the other. The longer the current continues, and the more intense it is, the more does the zone of anaelectronous gain upon that of kataelectronous, or, in other words, the more closely does the neutral point (*np*) approach the negative pole ($-p$). Consequently, when a strong current has passed for a length of time through a nerve, the zone of kataelectronous is a very short one, confined to the immediate vicinity of the negative pole.

When the particles of a motor nerve pass from a state of inertia to one of motility,—i.e., from one

of diminished to one of increased excitability,—the nerve is momentarily excited, and gives origin to an impulse. Therefore, when anaelectronous disappears in a nerve,—i.e., when a condition of diminished activity becomes one of normal activity,—an impulse is generated just as certainly as when kataelectronous—i.e., increased functional activity—appears in a nerve previously normal.

Suppose, in the accompanying diagram (first

figure), *cn* represents a nerve, and *m* the muscle to which it is distributed. If, then, a downward current be applied to this nerve, it is plain, $+p$ being the positive pole and $-p$ the negative, that *a* will be the zone of anaelectronous, *np* the neutral point, and *k* the zone of kataelectronous. When the circuit is closed in obedience to the law already enunciated, an impulse starts from *k*, and, in order to reach *m*, has to pass only through the stretch of normal nerve between $-p$ and *m*. Therefore this impulse of circuit-closure reaches the muscle unimpaired.

Again, when the circuit is broken, the impulse which is generated in *a*, in order to reach the muscle travels only through the zone *k*, whose conducting-power is increased, and a portion of normal nerve; consequently it also reaches the muscle unimpaired. It is plain, then, that with *descending currents strong movements must be induced, both at the making and at the breaking of the circuit.*

With *ascending currents* the results are different. Thus, in the lower figure of the above diagram, *cn* = nerve; *m* = muscle; $+p$ = positive pole; $-p$ = negative pole; *np* = neutral point; *a* = zone of anaelectronous; *k* = zone of kataelectronous. Now, it is plain that the impulse generated in *k* at the closing of the circuit must pass through *a*, the zone of diminished conducting-power, in order to reach *m*. Consequently, with the ascending current the contractions of circuit-closure are very feeble, or are altogether wanting. When, however, the circuit is broken, the impulse generated in *a* reaches the muscle *m* unimpaired.

Without occupying more space with a discussion of the subject of electrotonous, but contenting myself with the statement that these facts and reasonings apply especially to such currents of moderate strength as are with propriety employed in therapeutics, it is plain that descending currents ought to be more efficient in inducing contractions than are ascending currents. What science thus has discovered, clinical medicine has also found out: descending currents are in practice more powerful than ascending currents, as I shall take occasion to show you repeatedly in the course of the winter.

From what has been already said, it is so evident as scarcely to need further demonstration that the breaking of a current running in one direction must render the nerve more sensitive to the closure of

a current running in the opposite direction, but less sensitive to the closure of a current running in the same direction; for when the currents pass in opposite directions anaëlectronous suddenly becomes kataëlectronous,—*i.e.*, that which was below normal suddenly becomes above normal, whilst with parallel currents anaëlectronous remains anaëlectronous.

To make this more clear, however, let us use the following diagram. In it the letters have the same

significance as in those previously used, whilst the arrows on the side of the lettering represent the direction of the current to which the lettering applies.

The downward current is supposed to be broken, and to be followed instantly by the upward: of course the upper, *a*, changes into *k*, and a doubly powerful impulse is sent down to *m*. Now the upward current is broken, and the downward sent through the nerve; at once the lower *a* becomes *k*, and *m* receives again a doubly powerful impulse.

The practical application of this reasoning is a very apt one. It becomes, in the first place, very plain why the secondary to-and-fro current of the induction coil has so much more power over muscles than has the primary induced current or the chemical current, as ordinarily applied.

If, however, instead of the chemical current being simply interrupted, its polarity be suddenly reversed at brief intervals, all the effects of the to-and-fro induction current upon healthy muscle are obtained. More than this, for reasons to be hereafter adduced, in certain muscular paralyses I have found that muscles which fail to respond to all other currents respond readily to a very slow to-and-fro chemical current.*

Having obtained an idea of the manner in which galvanic currents produce muscular contraction, it certainly is next in order to study the proper methods of applying those currents. When the poles of a battery of sufficient power are brought into contact with the human body, as every one knows, the current forces its way through, but it is of the utmost importance to determine by what route or routes it passes. The body as a galvanic conductor is governed by ordinary physical laws, and consequently some knowledge of these laws is a necessity to the electro-therapeutist.

If a current be passing along a homogeneous conductor, such as a wire of iron, of copper, or of other metal, and that conductor splits up into a

number of branches, the current also divides, as is illustrated in the accompanying diagram. If these

branches, being of equal size and length, offer an equal resistance, the current divides equally; but if the size or length, and consequently the resistance, of the branches be unequal, the division of the current is unequal; the law being that the strength of the current in each branch of the conductor is inversely proportional to the resistance of that branch. This law is as applicable to conductors composed of many substances as to those composed of a single substance; but then the resistance in a branch depends upon the specific resistance of the substance of which it is composed, as well as upon its size and length.

In applying these laws to the passage of galvanism through the body, it must be borne in mind that the dry skin offers an enormous resistance to the passage of the current, so that practically none of the latter will pass along it. On the other hand, when the skin is thoroughly wet with salt water it allows the current to pass through it readily.

Let us suppose, then, that in the following diagram $+p$ and $-p$ = wetted poles; *ss* = skin,

with the tissues below it. It is evident that, if the tissues were a uniform mass, the current, passing through the skin as a solid bolt, would break up into an infinite number of curved currents, which would meet and pass through the skin again as a solid mass at $-p$. It is equally plain that, of these sub-currents, those whose course was nearest the straight line from $+p$ to $-p$ would be the shortest, and would, therefore, meeting with the least resistance, be the strongest, whilst as the curve and consequently the length and the resistance increased, the strength of the current would diminish until it became practically null. In this imaginary case, the tissue beneath the skin has been supposed to be homogeneous: in actual life the tissue never is homogeneous, and the resistance of the different constituents varies very much. Consequently, the strength of the subdivisions of the current is greatly modified: those branch streams being increased which run along or through tissues that conduct readily, and *vice versa*.

By remembering these facts, we are enabled to apply electricity as closely as may be to any desired

* I am indebted to my friend Mr. Otto Flemming, electrician, of this city, for inventing, at my suggestion, an automatic commutator or polarity changer, enabling the operator to obtain a regular to-and-fro chemical current. The following brief technical description of it may enable any one desirous of making one to understand the mechanism.

The clock-wheel gearing into a train of wheels of an ordinary clock is fastened on a shaft, to which are also attached three insulated metal disks, the two outside ones of which, by means of light springs sliding on them, conduct the current direct from the battery over the centre disk, which, consisting of two metal halves, conducts either pole of the battery, when the clock-work is in motion, alternately to the springs, and thence to the electrodes.

portions of the body. Thus, if it is intended to affect as exclusively as possible a certain spot or minute portion of a nerve, a well-wetted small electrode is passed directly over this portion, and, especially if the latter be somewhat deeply situated, pressed down firmly, so as to condense the tissues as far as possible into a homogeneous mass, whilst a large wet electrode is placed at a small distance from it in a situation which the anatomy of the part will readily suggest. The following diagram will perhaps illustrate this point more clearly than will many words.

It is evident that the spot directly under the small electrode will receive the full strength of the current, which is directly afterwards so broken up as to affect very slightly any other part.

The practical importance of a knowledge of these laws is very evident. Thus, suppose it is desired to pass a current through some length of a nerve; it is evident in the first place that two small electrodes should be chosen, and that they should be well wetted and pressed firmly upon the trunk of the nerve at the two ends of that portion which is to be affected.

Again, in applying electric currents to muscles it is found that if the currents be sent through the body of the muscles, only very imperfect and partial contractions occur, unless indeed the current be an excessively strong one. Duchenne was the first to discover that when one pole is placed over spots or points in the muscle, violent general spasms of the muscle are produced by currents usually too feeble to elicit a distinct response. To these places the name of *motor points* has been given. These motor points correspond to the position at which the supplying nerve enters the muscle.

As the therapeutic value of a current in paralysis depends not so much upon its direct influence on the muscle as upon the contraction which it causes, it is plain that the current ought to be sent through the motor points. This is evidently best accomplished by using one small well-wetted electrode pressed firmly over the motor point, and another large sponge electrode placed at some little distance from it, in the manner which has already been explained.

We have now, gentlemen, been over all those points concerning the relations of galvanic currents to healthy muscles, and are ready to study their relations to diseased muscles.

If a muscle by destruction of its supplying nerve be cut off from all spinal influence, it rapidly undergoes a degeneration. In the course of a very few days it will be found upon testing that it no longer

responds to a rapidly interrupted faradic current, but does respond to such current when slowly interrupted; a couple of days later, and the muscle fails to contract to the most powerful and most slowly interrupted induced currents. When, however, the continued current is applied, and is very slowly interrupted, or, better still, if it is reversed at intervals of one or two seconds, contractions are produced. It is this fact which has led to the belief that there is some intrinsic and inscrutable difference between the induced and the chemical currents. But, gentlemen, remember that time is an element required for the propagation of any force. If you pass your hand rapidly through a flame, the latter is not felt; if the hand move more slowly, a sensation of warmth is perceived; if the motion be still slower, this sensation becomes pain. Now, if the hand be partially anæsthetic from disease, in order for the sensation of warmth to be perceived motion must be much slower than in the first instance. In other words, more time is required for the partially paralyzed sensory nerve to perceive heat than for the normal nerve to do so. What is true of the sensory nerve is true also of the motor nerve. It does not respond so quickly to stimuli when partially paralyzed as when normal. The muscle first loses its power of responding to those galvanic currents which are excessively rapid, then to those which are less so, and finally to all induced currents, because from their very nature these currents, even when slowest, last but a fraction of a second. The chemical current may be continued for any length of time at the will of the operator, who is thus enabled to act upon a muscle whose nerve has become so insensitive that it fails to perceive the flash of faradic galvanism.

Some of you, no doubt, are already saying to yourselves, This is all very pretty theory; but what proof have you? The proof is this: when a chemical current is rapidly interrupted it is no more able to affect these abnormal muscles than is the faradic current. I have observed this over and over again in the clinic, and am fortunate enough to be able to demonstrate it to you to-day on two cases.

This man is suffering from a palsy of about one week's standing, due to the pressure of exudation upon the facial nerve. I now apply the electrodes of a very powerful faradic battery, and, though the man winces from the pain, yet not one of the affected muscles moves. I now substitute a rapidly interrupted chemical current from forty cells, but still no effect is perceptible. I will not move my electrodes (which are really on the motor points), but let the assistant stop the interruptions and himself break the current about once in two seconds. You see now how the whole side of the face jerks. (A demonstration on the second case, a child suffering from very recent infantile paralysis, yielded similar results.)

DEATH FROM CHLORAL HYDRATE.—The death of a young man is recorded in the *Canada Lancet* for December, as following in about twenty minutes the ingestion of about three drachms of chloral.

ORIGINAL COMMUNICATIONS.

CLINICAL NOTES AND REFLECTIONS.

BY WILLIAM HUNT, M.D.

MEASURING.

WHAT hospital surgeon has not fretted over a fractured thigh that would not come down or do as he wished it to do? Time and again he measures, and his assistants also do it, but things will not come right, and no two agree exactly in their opinions as to the same case. All points of departure are taken,—sterno-clavicular junction, umbilicus, anterior superior spine,—and all with the same results. Light has suddenly broken in, at least upon us at the Pennsylvania Hospital, as to these difficulties. It is well known that bilateral symmetry may be said not to exist as to breadth,—but has it ever occurred to any one to state as a law that *bilateral symmetry as to length is exceptional*? That is, most people are longer on one side than on the other.

Dr. Cox, formerly resident of the hospital, and Dr. Morton's assistant, noticed these discrepancies and measured both sides of a large number of persons who had never received any injury whatever to their lower extremities, taking his points of departure from the various positions on the trunk above indicated. I have his full permission to state that the differences between the two sides ranged from seven-eighths of an inch to nothing, and that the latter result was exceptional. The doctor has also the data as to right and left, and the result will soon be published. If this statement holds good, how many heretofore puzzling things are explained, and what a nut to crack for those who dogmatically assert that a man with fractured thigh *must* be cured without shortening! Let us put it in this way: his limb *should* be cured so as to be as nearly as possible what it itself was before the injury was received. We must combat the shortening from overlapping, but we need not put the patient to torture in striving to force one side to be exactly like the other. I have never known the really forcible practice of treating fractures to do well. The muscles or the patient himself will be sure to rebel, and the results will not be as good as were hoped for. These facts explain what I have not unfrequently experienced. I have been much annoyed, for instance, by a thigh-case showing too much shortening while the patient was in bed. All would seem to be right at the point of fracture; but, when compared with the other side, the measuring was unsatisfactory. On getting up, however, the patient would show but very little difference, and after a little practice he would walk with scarcely a limp, or with none at all. These observations also explain, to a great extent, the varying gaits of different people who have never met with injury.

Wherein do these differences in the two sides lie as to the lower extremities? Hyrtl says the right arm is longer than the left by from two to three lines, but that the lower extremities are equal in

length. I have made a few measurements on the skeleton, and can confirm this statement, and, therefore, think that the variation is mostly an acquired one, and that it is dependent upon the carriage of the trunk, through occupation or habit, altering the direction of the spinal column. At all events, we know that quiet, well-formed, and healthy children, when they are the subjects of fractured thigh, do not present the same difficulties as to measurement.

This question of bilateral symmetry is one of great interest, and, so far as I know, it is by no means exhausted. We are right-handed simply because the right side is more developed in uterine life, it may be to accommodate the liver, and at birth it is the stronger. Hence the infant begins at once to use his right arm at the expense of the left. I think, if we could have the early history of a left-hander, we would find that some extraneous cause, say a hurt or some habit of nursing, restrained the free use of the right hand. Ambidexterity, I think, is altogether acquired. Dr. Leidy has suggested that if it exist naturally anywhere we should find it among the Indians, and he intends to make some inquiry about it.

I do not know what the received ideas of aphasia are at present, but I have never subscribed to the doctrine of a left centre, believing that it is only more developed than the other, in accordance, it may be, with its connection with the right side of the body. Anatomy and physiology alike are, in any organization practically symmetrical, against a unilateral centre for a bilateral function.

TEN-YEAR SURGERY.

It has often been said, "How instructive it would be if our old patients were to present themselves to us for examination after ten years or more had elapsed since they were under care!"

I am able to report two cases of great interest that more than average this requirement as to time.

In *Hays's Journal* for April, 1865, I gave a detailed account of a case of match-maker's disease, or phosphorus-necrosis. I removed the whole of the right side of the jaw, all of the symphysis, and part of the left side. The peculiarities of the case were, that I operated altogether by internal incisions, and saved the periosteum by pushing it from the bone with the blunt-edged elevator of the trephine-case. Before the anterior muscles and membrane were detached from the symphysis, the tongue was secured from being swallowed by passing a ligature through it and looping this around the ear.

In November, 1874, a man was admitted into Dr. Morton's ward for this disease in the upper jaw. It was found that he came from the same establishment where my patient was formerly employed, and he was able to give his address. My man was found, and kindly came to the hospital and was shown to the class by Dr. Morton along with the new case. He was in perfect health. A new, well-formed, somewhat contracted, firm, and undoubtedly bony jaw occupied the place of the old diseased structure. The man had no difficulty in eating anything. His beard concealed all unevenness of feature, which was not very great. What

particularly interested and surprised me was the *shape* of the new part. Instead of there being a mere curved line of hard substance leading from the condyle forward, there were *ramus, angle, body, and symphysis*, as though the new bone had been cast into a periosteal mould.

While preparing this article for the *Times*, a man walked into my office with a freedom that suggested *nothing about eyes*, and said, "Are you Dr. Hunt? I have never had a good look at you, and wish to see you. I am here on business, and am going away to-night. I owe you much, and will never forget you; *but may-be you can do something more for me*. Do you remember S—, of Illinois, upon whose eyes you operated at Wills Hospital in 1858?" I said, "Certainly I do." "Well," said he, "I am the man." Now, I am not going to relate here an ordinary case of successful cataract-operation; but the history is this. S. was the son of a farmer; was fourteen years old when he was brought to Wills. He was practically blind from birth. There is some discrepancy in statement as to the early condition of his eyes; but, at all events, he had no recollection of ever having seen. He was healthy in other respects; had never been to a school for the blind, but was bright, as people usually are who have to feel their way through the world. Dense white capsular cataracts occupied the pupils of both eyes. There was great nystagmus or oscillation of the eyeballs. The boy was etherized, and I performed extraction, making the corneal incisions with a lance-shaped knife, and removing the cataracts with the fine hooks and forceps of the eye-case.

The bodies of the lenses, if there had ever been any, were absorbed, as the opaque material seemed to be merely thick membranous substance.

The boy did well, the wounds healing nicely; but when we exposed him to light we found that we had a veritable Casper Hauser to observe! He was a grand confirmation of touch being the master-sense and the only one by which we originally establish our relations with the external world.

He could have given a direct answer to the question of Molyneux to Locke, "Whether a blind man who has learned the difference between a cube and a sphere by the touch can, on being suddenly restored to sight, distinguish between them by the aid of the newly-acquired sense only?" Locke answered, theoretically, No! S. answered, practically and decidedly, No! He obtained no knowledge at first, by the eyes, of shapes, distances, sizes, extension, or consistence of objects; of color, of course, he had no idea. Everything, distant or near, appeared to be striking against him, or to be within him. Restrain his arms and hands, and he stumbled about worse, if anything, than before he was operated upon. Encouragement would cause him to move with care, but he was very much afraid. In fact, his sensations were more painful than pleasant, notwithstanding the good promise of the operation. He had to learn as a babe learns, who, in early life, grasps with equal confidence for the moon or its mother's breast. Its early days are occupied with a constant automatic struggle in correcting, by the

touch, the deceit of the eye. By-and-by experience settles the question, and it soon gives up its vain endeavors.

The nystagmus in S. continued, and doubtless added to his confusion of vision. In this condition his father took him home. I heard of him now and then as making some good progress, and then lost all knowledge of him. And now, on the 3d day of December, 1874, he walks into my office. His sight is good for all ordinary purposes; the nystagmus is gone, he distinguishes shapes, sizes, distances, and color without difficulty. He told me he was a long time in learning how to see, and at eighteen he went to school and learned to read with ease.

Dear me! when will people be satisfied? I said in the beginning of this note that he wanted me, if possible, to do something more for him. Well, he said he was a herder in winter on the prairie, and he now could not see a horse more than half a mile off, and he would like some far-reaching glasses so as to be able to take in six hundred head of cattle at once!

I was fortunate enough to find Dr. W. F. Norris at home. The doctor soon fitted him with the stretchers, much to his delight; and, as the train did not start till evening, he agreed to go to the University Hospital, where he was shown to the class.

Such incidents as these are very pleasant. I wish all that might turn up on the ten-year plan, as the insurance men say, could be so gratifying. I often wonder what becomes of them. May-be it is as well as it is. If another trumpeter were to blow the assembly for our cases, the muster might make us anxious to lay down our own horns.

CONSERVATISM.

A brakeman was brought into the hospital, who had fallen from the roof of a car while the train was in motion. He was perfectly unconscious; there was no fracture of the skull, but a lacerated wound of the scalp. There was vomiting of blood, which may have been swallowed. The left arm was completely crushed from the hand up to above the elbow. There was a fracture of the right radius, a large laceration near the right knee, and contusions generally. The shock was profound, and the case seemed hopeless. Restoratives were administered, and some reaction occurred, but there could be no thought of an immediate operation.

The patient could swallow liquids, and took nourishment in this form, although unconsciously.

Contrary to expectation, he continued to live, but delirium lasted for two weeks; there was great restlessness, and the broken right arm was tossed about as in a case of chorea.

In the mean time the left arm had become gangrenous, and the line of demarcation was forming. Consciousness returned partially at times. As there seemed to be a slim chance of the man's pulling through, the question was put to me by my assistant, Dr. A. V. Meigs, "Why don't you operate?" "Because," I answered, "if this man gets well at all, it is to be by a *natural amputation*. I shall simply remove the dead fragments as they separate, and

do not intend to touch him with a knife. His condition in other respects precludes it." "What do you gain by this procedure?" "I save injury to, and hemorrhage from, blood-vessels which are now sealed, and, above all, I save secondary shock from injury to great nerves, and thus perhaps we will save life also."

The plan laid down was strictly followed. The man was nourished, and in time I removed the gangrenous limb and fragments of bone. Some exuberant granulations were trimmed off, but neither skin nor muscles, great artery nor nerve, were touched with a knife. Recovery took place, with, in surgical parlance, a "beautiful" stump. (I never could see the beauty in these things; but language is imperfect.)

The patient also slowly recovered from his other injuries. His radius, from the tossing about in his delirium, was not united when he left the house, but he nevertheless had a very useful arm.

Now, the refreshing part of this case is this. During the progress of it I was actually reported to the managers of the hospital by some of the man's friends and minor railroad officials for neglect, inasmuch as they thought I was *doing nothing* for him. A committee was appointed, and the matter was looked into and explained. The man himself did not know of these procedures until afterwards. He could well have said, "Save me from my friends." I said refreshing, but, on the whole, I think discouraging would be the better word.

ANALYSIS OF ONE HUNDRED CONSECUTIVE CASES OF LABOR.

BY CHARLES W. BROWN, M.D.,

Mansfield, Pa.

THE following notes are based upon one hundred cases of labor in succession, as they occurred in my practice.

There were twins, 2; single births, 98. The presentations were as follows: hand and arm, 1; brow, 2; foot, 1; vertex, 82; of which 67 were first presentations, 4 in the second, and 9 in the third. Of the children, 59 were males, and 43 females, of whom two males and two females at full term were still-born. There were 12 premature labors, of which 11 were still-births. Of the mothers, 64 were multipara, and 36 primipara. Forceps were used in six cases, podalic version in two. Cord about child's neck, 5. The nativity was—American, 92; German, 4; English, 1; French, 2; Swede, 1.

Prolapse of the cord. Case 26.—Age 35; a large, healthy multipara. I saw her after the labor-pains had been very hard for nine hours, and found a large sac of waters presenting at the vulva, the os fully dilated. I ruptured the membranes, and a large amount of liquor amnii escaped, bringing down a long loop of the cord, which I tried to replace by placing patient on her knees and breast; but the pains were so strong and frequent that all efforts failed. It was but a short time before the cord ceased to beat; in twenty minutes labor was completed, with a still-born child, which it was found impossible to resuscitate.

Placenta prævia centralis. Case 32.—Age 30; multipara; a large plethoric woman. At 8 P.M. I found that she had been flooding some during the day, and as the pains grew harder the hemorrhage increased. The os was dilated sufficiently to admit two fingers, the placenta presenting. The fingers were passed around gently, peeling off the placenta, and at the same time dilating the os; in a short time I succeeded in removing the placenta whole, and then passed the hand in, and, grasping both feet, brought them down, and delivered, as speedily as possible, a still-born child. The usual means of resuscitation were resorted to, but without success. The amount of blood lost was not large, and the patient made a rapid recovery.

Distorted pelvis. Case 49.—Age 20; a very small woman, who had hip-joint disease when a small child; the right leg is no larger than when five years old. After twenty hours of hard pain, the head was resting in upper strait; the os was rigid, but was forcibly dilated by the fingers, so that the forceps would pass through; they were applied with great difficulty, owing to the narrow, deformed condition of the pelvis, the right side of which was so contracted that the head had to pass directly to the left before descent could take place, so force was applied by the forceps in this direction. After two hours' steady work, using great force, and readjusting the forceps when rotation took place, and compressing the head as much as possible, I succeeded in delivering a male child weighing twelve pounds. It was thought that it could not be delivered without craniotomy, and my friend Dr. S. was summoned for this purpose; but labor was completed on his arrival. The woman made a good recovery. Measurements of this pelvis were not taken, but the forceps would barely pass when locked, so narrow was the transverse diameter.

Case 48 was reported in No. 106 of the *Times*.

Case 29.—A large, healthy woman, age 28; Swede; multipara. When I arrived, I found one child had been expelled while she was walking across the room, the child falling to the floor, breaking the cord. A lady who was present tied the cord, and cared for the little one. Finding that it had received no serious injury, I laid it to one side to be washed and dressed with its coming brother. On examination I found a hand and arm presenting. I passed the hand up between pains, grasped one foot, brought it down, and in a short time delivered the second healthy male child. There were two distinct placentas—one attached to each side near the fundus. Three years before, the woman had twin girls.

Case 15.—Age 20; primipara. When I arrived, I found the child expelled, lying in bed, dead. Two young women were present, and did not dare to remove the clothing to care for the child, so had let it lie until my arrival, half an hour after it was born. They said it cried when it was first expelled, and it had been allowed to lie there and suffocate.

Case 33.—The mother was 13½ years old; both she and the child did well.

Case 21.—The mother was 45 years old.

Case 40. *Mother's marks.*—Mrs. F., age 35; has had three perfectly-formed children. Natural labor; female child, with double hare-lip and double cleft palate. A girl eighteen years of age, who had a hare-lip, was employed to do house-work during the whole of gestation. Mrs. F. said she always dreaded to look at the girl, but had no idea that her child would be deformed. Whether this girl with hare-lip was the cause of the child's deformity, I shall not attempt to decide.

Remarks.—In all cases where the os is dilated or dilatable and the pains are weak, I am in the habit

of giving quiniæ sulph., gr. v, with ten to twenty drops fluid ext. of ergot; and where the os is not dilated, if the strength of the patient is failing, I give quinia every two hours to prevent exhaustion. When the os is found back towards the promontory of the sacrum, I introduce one or two fingers and draw it forward towards the pubis between the pains, and hold it there until it will remain. I do not support the perineum, as is recommended by many authors, but if the pains are very strong, and the perineum rigid, hot fomentations are used over the vulva, and sufficient pressure is put on the head during the pain to give time for the parts to dilate.

The placenta is delivered by passing the right hand into the vagina, using the cord as a guide up to the placenta, and placing the left hand over the uterus above the pubis and making gentle pressure with a kneading motion, at the same time, with one or two fingers of the right hand, starting the nearest edge of the placenta loose, and causing it to roll up and come endwise, instead of drawing on the funis and forcing it to be expelled sidewise. As the placenta is expelled, I follow down the womb with the left hand; by this means very rarely is any other force than the contraction of the uterus needed to expel the placenta.

Metritis and metropéritonitis occurred in seven cases. These were treated by full doses of morphia, aconite, veratrum viride, and an ointment applied to the abdomen of opii pulv. \mathfrak{z} i, camphoræ pulv. \mathfrak{z} i, adeps \mathfrak{z} ii; mix; with hot fomentations. No cathartics were given until soreness and tympanitis had all disappeared. No maternal deaths have occurred in my practice.

No anæsthetics were used. Patients did not complain of much more pain when instruments were used than with natural labor-pains.

NOTES OF HOSPITAL PRACTICE.

BELLEVUE HOSPITAL, NEW YORK.

CLINICAL SERVICE OF FRANK HASTINGS HAMILTON, M.D.,
Prof. of Surgery at the Bellevue Hospital Medical College.

RUPTURE OF A LIGAMENT.

THE next patient is a laboring man, who was standing on his right knee with the back of the corresponding foot directed towards the ground, when a weight fell upon the back of his legs, causing a rupture of the anterior fasciculus of the external lateral ligament of the ankle-joint. This ligament is very feeble, and is easily ruptured. If the internal ligament is torn, the foot is apt ever afterwards to turn out; but the function of the external ligament is less important, and no deformity is likely to ensue. A few days' rest is all the treatment that is required.

ATROPHY OF THE PLANTAR MUSCLES.

This man came to me thinking he had rheumatism of the foot. When he took off his shoes the first thing I noticed was that he had a flat foot. "The hollow of his foot made a hole in the ground." Both of his feet were in this condition. The ligaments which support the lateral and antero-posterior arches of the feet had given way. Such a man could not walk well. He

would not make a good soldier. This condition probably gave a predisposition to the special malady under which he is now suffering; and in addition he has been working in a damp basement as a fireman. He now finds that his left foot is cold, and that he cannot sustain his weight upon the ball of the foot. It has no strength, but it is not tender and swollen. Looking at the bottom of this foot, I find that the plantar muscles are wasted. It is evident, therefore, that the foot is suffering from defective innervation. I recommend galvanism, and warmth.

ULCER UPON END OF STUMP—TREATED WITH WARM WATER.

I amputated this man's leg below the knee three or four years since. The wound healed kindly, and he has for some time worn an artificial limb, but recently he fell and tore open the cicatrix. A large ulcer now exists upon the end of the stump, with indurated edges. It is being treated with warm-water fomentations, under which applications the callous edges are disappearing, and the granulations are filling up the centre and base of the ulcer.

ACUTE ORCHITIS.

Here are two examples of acute orchitis, with some inflammation of the cord and of the epididymis in each case. In both cases, also, we notice, some serous effusion has taken place into the tunica vaginalis. It is of interest, also, to note the fact that in both of the cases the patients ascribe the inflammation to a strain in lifting. I have met with frequent examples in which the occurrence was ascribed to the same cause; yet it is not easy to explain why lifting should produce such results. The patients are being treated by rest in the horizontal position, suspension of the testes, and a tobacco-poultice. They are both improving.

DISLOCATION OF THE SHOULDER OF FOUR WEEKS' STANDING.

This woman claims that she is only forty-eight years old, but she is certainly fifty-eight. She is very fat. The dislocation is subglenoid. (Dr. Hamilton here called attention to the several varieties of shoulder-joint dislocations, and to the differential diagnosis. Especial emphasis was placed upon two points as distinguishing a dislocation of the shoulder from a fracture of the surgical neck of the humerus. First, Duga's test: placing the hand of the injured limb upon the opposite shoulder. If it is a dislocation, the elbow will project in front of the body; if it is not, the elbow will rest easily against the chest. Second, placing the hand over the acromion process, like a saddle, with the fore-fingers resting upon the front of the shoulders, while the thumb rests against the back, and then swinging the arm backwards and forwards: if the head of the bone is in the socket, it can be felt distinctly as it moves backwards and forwards.)

Several attempts have been made to reduce this shoulder, and she has just come from the dispensary, where, under ether, Dr. Bryant, an experienced surgeon, has made long-continued and varied attempts at reduction. She has scarcely recovered from the effect of the ether, and considering the age and condition of the patient, together with the amount of skill already employed, it seems probable that reduction could not be effected. At any rate, it would be proper to defer the attempt to a later day. If reduction were never effected, she would be maimed somewhat; yet often, in these cases, a very useful limb results.

PARTIAL MUSCULAR ANCHYLOSIS AFTER REDUCTION.

This man received a blow upon the upper end of the humerus, causing a dislocation into the axilla,—subglenoid. It was reduced promptly by Dr. Burge, of Brook-

lyn, the patient being anæsthetized. After several weeks he has called upon me, because a physician has told him it is not reduced. I find the head of the bone in its socket, but he is suffering from a certain amount of muscular ankylosis. He cannot lift the arm freely, in consequence of a contraction of the lower fibres of the pectoralis major and of the latissimus dorsi. He has kept his arm too long against the side of his body, and if he continues to hold it in this position the ankylosis will become complete. He must move it about freely, and some one must lift it up forcibly every day, even though it hurts him a little.

TRANSLATIONS.

ACTION OF THE BILE SALTS ON THE ECONOMY.—MM. Feltz and Ritter continue their interesting contributions to our knowledge of the bile in a communication bearing the above title, which was published in the *Journal de l'Anatomie et de Physiologie*, No. 6, Nov. et Déc., 1874.

After giving a detailed account of the exact and tedious processes employed by them in obtaining the glycocholate and taurocholate of sodium from ox-bile in a perfectly pure condition, and the process followed for the detection of the biliary acids in the blood and urine, they give at some length the general process for the analysis of these latter. They then describe their experiments in full. The first series included injections of a mixture of the biliary salts as they are found in ox-bile. These were dissolved in water in the proportion of twenty per cent. of the anhydrous salts, and small quantities were injected into the veins of dogs. From this first series of experiments it appears that the bile salts are very powerful toxic agents when injected into the blood in considerable quantity. The economy reacts energetically, and seeks to throw off the poison by every possible avenue. The exaggeration of all the secretions, the pytalism, the rhinorrhœa, the abundant urinary secretion, the diarrhœic stools, observed in the animals experimented upon, are thus explained. While nothing checks this elimination, the normal condition becomes re-established after some days.

The intoxication is manifested particularly by the alteration brought about in the blood, chiefly in the blood-globules. The latter are dissolved; the blood becomes diffuent, and the coloring-matter escapes with the urine. Intestinal and buccal hemorrhages are frequently produced, resulting from ruptures of the capillaries brought about by difficulties of the capillary circulation from modification of the blood. In some instances the coloring-matter of the blood becomes crystallized. The appearance of biliary coloring-matters and sometimes of indican in the urine is worthy of note.

It seems possible that the condition of granular and fatty degeneration observed in some cases may have been due to the gradual action of the poisons. In this respect poisoning by the bile salts resembles phosphorus-poisoning, but it is clearly differentiated by the absence of those muscular lesions so characteristic of the toxic action of this metalloid.

The symptoms which are observed in icterus, and which they have been able to reproduce, are cooling, diminution of the pulse, and some one of the modifications of the urine. They felt themselves justified, then, in supposing that a certain number of the phenomena observed in icterus should be attributed to the biliary salts,—notably the hemorrhage and convulsions.

Would it be rash to affirm that these accidents, which often appear in the course of icterus with formidable gravity, depend upon individual conditions which exaggerate the secretion or the retention of these salts?

They felt, besides, the more authorized in affirming this pathogeny of the graver accidents of icterus, since the lesions of the liver, the kidneys, and the blood are in great part those which are attributed by authors to icterus gravis. The mixture of the two salts having produced such a marked effect, the next point was to find whether this was due to the action of both salts in combination, or whether the active properties resided in one alone.

For this purpose the taurocholate of sodium, prepared by a process of which MM. Feltz and Ritter give full details, was employed. Injections were made into the veins of dogs as in the previous series of experiments, when it was ascertained that the same series of phenomena were induced as when both salts were employed.

Injections of glycocholate of sodium, made in a similar manner, gave rise to certain nervous symptoms, which might have been due to the effects of previous loss of blood.

In comparing these various experiments, say MM. Feltz and Ritter, the closest analogies may be observed between the action of the two salts in mixture and that shown by either one when employed by itself. Large doses rapidly injected always caused death; smaller doses provoked accidents which, formidable at first in many cases, rapidly disappeared when there was time for elimination to become established.

Calculation of the proportion of each dose to the weight of the animals showed that, in similar doses, the mixture of the biliary salts was more energetic than the glycocholate alone. The taurocholate was more active than the mixture of biliary salts.

Believing that it is not possible to deduce from physiological experiments made upon animals conclusions which can have high scientific value, the authors formulate the result of their experiments with considerable reserve as follows:

Taurocholate of sodium is more active than glycocholate; the mode of action of the two salts is identical—both decompose the blood-corpuscle.

Continuing their researches with the taurocholate of sodium, which offers better opportunities for study than the glycocholate, MM. Feltz and Ritter instituted a series of experiments with this salt injected in quantities so small as not to produce immediate accidents. The result showed decided modification of the humors. The quantity of urine diminished, coloring-matters of the bile, indican, albumen, and, occasionally, blood, appeared in it. The acidity of the urine diminished; in some cases it even became alkaline; the urea diminished sensibly, while the uric acid was increased. The animal's temperature became slowly reduced.

The blood was altered more or less profoundly, the corpuscle becoming deformed; the proportion of fatty matters and of cholesterin was augmented. Experiments made upon the gases contained by the blood showed that the biliary salts modify not only the form of the blood-corpuscle, but also its constitution; the hæmoglobin itself becomes altered, thus bringing about disorders of nutrition and circulation. X.

A CASE OF POPLITEAL ANEURISM IN A WOMAN CURED BY DIGITAL COMPRESSION AFTER FAILURE WITH CARTE'S COMPRESSORS (*Canada Med. and Surg. Jour.*, Dec. 1874).—Dr. John Reddy reports the case of a woman, æt. 59, who suffered from a large, sacculated popliteal aneurism. Carte's compressors were applied, and were retained for about seven weeks, with only slight good results. Digital compression was then tried, and in twelve hours neither bruit nor pulsation was distinguished. It was kept up for twelve hours more, and resulted in a perfect cure.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF
MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JANUARY 16, 1875.

EDITORIAL.

BILLS.

WE have received several communications in regard to our editorial on professional bills. One correspondent from Boston sends us a blank form which he uses, and which he says is very commonly employed in that city. The front of the bill presents nothing unusual, but on the back of it is printed as follows:

THE BOSTON MEDICAL ASSOCIATION, composed of the regular physicians of Boston, adopted the following Fee-Table, July 1, 1864.

But it is left to the judgment of each practitioner to make any deduction from the following rates which the pecuniary circumstances of the patient may require.

For each visit, within the city, in the daytime	\$3.00
For a visit after 9 P.M. and before 8 A.M.	\$5.00 to \$10.00

(In cases of consultation or other extraordinary attendance in the night, the fee for such extra attendance shall be added to that for a night visit.)

For a visit in consultation	\$5.00 to \$10.00
For attendance involving travel out of town, mileage shall be charged at a rate per mile, for short distances, of	\$1.00 to \$2.00

For advice at the physician's house, according to the importance of the case, unseasonableness of the hour, or time occupied	\$3.00 to \$20.00
--	-------------------

For Vaccine Inoculation	\$5.00
-----------------------------------	--------

For attendance in Midwifery in the daytime	\$20.00
--	---------

For " " in the night	\$30.00
--------------------------------	---------

(Obstetric Operations, when necessary, shall be charged in addition to the usual fee for attendance. In obstetrical practice all subsequent visits shall be charged as in ordinary cases of attendance.)

For Minor Surgical Operations, such as stitching wounds, opening abscesses, etc.	\$5.00 to \$25.00
--	-------------------

For Major Operations, according to importance	\$25.00 to \$500.00
---	---------------------

(After surgical operations, all subsequent visits shall be charged as in ordinary cases of attendance.)

A correspondent in this city says, *inter alia*, "Your article on 'Bills' is thoroughly just. The profession has little idea what injury it does itself by its careless and unbusiness-like way of managing the business part of its duties. Patients have an undoubted right to know exactly what services they are paying for, and they will pay much more cheerfully for knowing." He has sent us his own private printed fee-bill or tariff of charges, which are eminently satisfactory from a professional point of view. He states that he hands this to his patients at their first visit. We are glad to know that there is one physician in Philadelphia willing to state publicly that his charge is five dollars a visit.

THE MEDICAL SERVICE OF THE ARMY.

THE grievances, desires, and necessities of the army medical service have been so thoroughly and almost unendingly discussed that all of our readers are, no doubt, sufficiently posted upon the merits of the case. There is scarcely room for any difference of opinion on the matter, and we believe a singular unanimity prevails in the profession, from Key West to the extreme northwest corner of Oregon. What is wanted to effect the desired change is *personal effort* on the part of *individual* physicians. Passing resolutions in County Medical Societies is all very good, but we doubt if such action accomplishes much. Plain, straightforward, earnest appeals to members of Congress from their medical attendants or from other physicians of local eminence in their various congressional districts, if persistently and urgently made, would certainly have an overwhelming influence. Will our readers make such efforts?—approaching their respective representatives personally or by letter, with the set determination to carry their votes? Any one willing to work, and lacking the necessary information, can obtain, we believe, the requisite documents by writing to Dr. J. M. Toner, Washington, D.C.

DEATH FROM METHYLENE.

A DEATH from the inhalation of the bichloride of methylene, which recently occurred at the Royal London Ophthalmic Hospital, is reported in the London *Lancet* for December 19. The patient was a woman 25 years of age; the operation a trifling one. The anæsthetic was administered by an experienced, careful surgeon. Three drachms by measure were poured into the perforated leather inhaler, covered with flannel on the inside (the ordinary quantity for an adult being four drachms). At

the end of about two minutes after the inhaler had been placed over the mouth and nose of the patient, her breathing suddenly became loud and stertorous.

The anæsthetic was at once discontinued, and the operation commenced. When the inhaler was removed, the lips and cheeks were ruddy, but an unusual pallor of the alæ of the nose and skin around the mouth was noticed. The respiration, however, continued deep, full, and exaggerated. The inspirations were accompanied by loud palatal stertor, and the nostrils were observed to be flaccid, but there was no impediment to free access of air to the lungs. Some seconds afterwards, the pulse at the wrist rapidly failed, and then ceased almost suddenly, but the respiration continued for some time, and then failed rather suddenly. Every effort at resuscitation was made, without effect.

DR. MARY PUTNAM JACOBI, during a recent meeting of the New York Pathological Society, temporarily occupied the chair during the presentation of a specimen by the President. We are informed that she has been elected delegate to the New York State Society from one of the local societies, and that it is intended to send her as a delegate to the next meeting of the American Medical Association.

PROF. AGNEW has declined the position of Corner's Physician, and deserves the thanks of the local profession therefor. It is a good and, in this community, a rather rare example for a man to refuse a lucrative position because his special knowledge does not fit him for it, or because his work must be done by proxy.

CORRESPONDENCE.

TOKIO, JAPAN, Nov. 23, 1874.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—You asked me when I left America to write you from time to time on medical subjects. I have been in Japan about one year, and am only now becoming familiar with its peculiarities. There is one disease found here which I have never seen described in any medical work or journal; it is called "Japanese leprosy." I have been so fortunate as to see four cases,—two very perfect ones. One, a man 40 years of age, married, a samourai, that is, a two-sworded retainer of a prince. He had suffered some six years; the symptoms gradually increasing until, when I saw him, he was covered with brownish mahogany-colored spots, not elevated above the surface, varying in size from an inch to four or five inches in diameter; these were distributed over the trunk and limbs. His face seemed

entirely covered with this discoloration, some parts a lighter and some parts a darker shade. His legs were œdematous, as also was his face. The most astonishing peculiarity of this eruption was an entire loss of sensibility in these spots, whilst outside of their circumference he had perfect sensibility. Another peculiarity was œdema of the eyelids, with inability to close them. On his attempting to do so, a space of a quarter of an inch separated them. Beneath and throughout the conjunctiva was a deposit of brownish mahogany-colored pigment. This accumulation was greatest at the inner canthus. Another symptom, and, as the native physicians tell me, an infallible one in point of diagnosis, was entire loss of the eyebrows; giving the man a most curious expression. The hair of this patient's scalp had not come out, but in some cases it does so. The patient complained of no trouble elsewhere; no itching of the skin; urine high-colored, specific gravity normal. The only fault he had to find with his disease was the peculiar appearance it gave him, and the people in the public baths not liking to bathe with him. It is not a contagious disease. The skin on his face had a shining appearance, an important point in diagnosis. In the spots on his limbs I thrust needles to the bone without detecting the slightest sensibility; this, too, is diagnostic. The disease is hereditary and considered incurable. I placed the man under treatment with cod-liver oil, iron, good food, beef, etc. He continued to improve slightly until an insurrection broke out in his province, Saga, when I lost sight of him.

The second case was very similar, with few exceptions. In this case the eyebrows had not been entirely lost, his hair was coming out, and he had partial paralysis of lower limbs, also an endocardial murmur. I suppose this second case was complicated with "beriberi." This case, too, I have lost sight of, owing to the Formosan trouble. He was placed under the same treatment, with digitalis added. I am sorry that I am unable to give you any further points on these cases, but hope soon in my hospital practice to study the disease fully. I would further state that case No. 1 said that the exciting cause in his case was hardship and unwholesome food during an insurrection, and that his father had died from the same disease.

Hoping this description will interest you,

I remain yours, very truly,

A. S. ASHMEAD, M.D.

NEW YORK CITY, January 1, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

AT the meeting of the County Medical Society held a few days since, Dr. Abraham Jacobi read a very elaborate paper on a subject which is, just at the present moment, occupying a large share of public and professional attention,—that of *diphtheria*.

He dwelt largely upon the nature of the disease, and treated minutely the histology of diphtheria. To the general practitioner, however, his paper is mainly important as regards treatment.

He said the remedies which he uses are few in number and simple in character. Many cases he had not attended, because he believed he had prevented them. He did not speak of those members of a family who, being exposed, have fallen sick, and who are protected by the isolation of the patient under the same roof; but he spoke particularly of the preventive apparatus in the hands of every family practitioner. He looks after the mouth and the pharynx of the children among his acquaintances as a regular thing. Eruptions on the head must be removed, and glandular swellings around the neck prevented or speedily cured. The same may be said of nasal catarrh and catarrh of the pharynx. Hypertrophied tonsils must not be excised at a time when diphtheria prevails, for at such a time every wound is apt to become diphtheritic, and hardly any operation inside the mouth will heal without becoming diphtheritic. For the same reason he postpones almost every sort of bloody operation during an epidemic of diphtheria, if possible. Lately he had seen the whole wound of an operation performed by one of the most prominent operators in the city, in a house where there was none of this disease before, become diphtheritic and jeopardize the success of the operation.

He spoke of the chlorate of potassium and the chloride of sodium as means of preventing the disease. He did not, however, place much reliance on these agents as remedies in diphtheria, yet he gave chlorate of potassium in almost every case. The chlorate is a remedy eminently fitted for most sorts of stomatitis. The large number of cases of stomatitis and pharyngitis during the prevalence of diphtheria and other kindred complications justifies and requires its use. He gives it for its effect on the inflamed mouth and pharynx, but not for the diphtheria. It acts as a preventive by restoring the mucous membrane to its normal condition. He does not do much more in tonsillar diphtheria. As this is a benign affection, it is of much greater importance to prevent it from spreading than to remove it from the tonsils, where its connection with the systems of the blood and lymphatics is so limited. In order to have the full effect, he insists upon frequent administration. Doses ought to follow each other in rapid succession: at least every hour, every half-hour, or every quarter of an hour a small dose ought to be given, to keep up a constant control over the endangered mucous membrane with the remedy. From a half-drachm to a drachm may be given during the twenty-four hours. As many families are acquainted with the remedy and use it without being bidden, see to it that the dose is not too large. The death of Dr. Fountain, of Davenport, Indiana, and of many others, from overdoses of chlorate of potassium, ought to be heeded.

In mild cases of tonsillar diphtheria Dr. Jacobi sometimes tries to remove or destroy the membrane when the latter is accessible. He insists upon the latter being the case, because, in his opinion, the use of solid sticks or of the mineral acids has done more harm than good. Where he cannot reach the diphtheritic deposit and remove it thoroughly, usually with the con-

centrated carbolic acid, he lets it alone altogether. The experience is not new that abrasion of the mucous membrane and injury to the epithelium will spread this process in a very short time. In many of the simpler cases of tonsillar diphtheria, he gives chlorate of potassium combined with lime-water or tinctura ferri chloridi, 3ss to ʒij a day, and generally mixed with a little glycerin, for the purpose of keeping the remedy in longer contact with the diseased surface, if not for its own effects.

There is scarcely any fever which requires attending to, and rarely swelling of the neighboring glands. When there is, cold water or ice applications may be used.

Every individual case must be treated on general principles. The fever ought to be reduced by washing, bathing, or by suitable remedies, increased debility obviated, collapse attended to, also reflex actions, such as vomiting, and the like, relieved. Whether ether, wine, brandy, champagne, camphor, musk, ammonia, coffee, etc., are to be selected, the individual case can teach better than any one else. All these remedies are frequently unsuccessful because used too late and in too small quantities. Whatever is to be done in diphtheria must be done early. More than anything else, the doctor urges attention to feeding. Remembering the greediness of lymph-vessels when the chyle-vessels are not supplied, he feeds as well as the digestive powers of the patient will permit, always keeping in view, however, the fact that the stomach of a fever-patient must be carefully looked after.

In regard to another class of diphtheria, everything depends on doing the right thing at the right time,—that is, the early time. He referred to nasal diphtheria. Most of these cases originate in the pharynx, and reach the nose by ascending to that locality. When a case of this kind is just established in the nose, it shows itself very soon by a peculiar thin discharge, not at all copious, and by a very early swelling of the glands of the neck. In both of these classes of cases, the local treatment has to be commenced at once; and in a large majority of cases the treatment will be successful.

What are the dangers of nasal diphtheria? Rapid absorption, putrefaction, inhalation of vile smells. The indications are clear enough. The surface of the nose must be cleansed and disinfected. When you begin early, the layers of epithelium are less liable to be involved in the diphtheritic lesions. Your disinfectant will then be successful, and your injection will wash the surface clean. No strong disinfectant is required: two or four grains of carbolic acid to the ounce of water is enough. Injections must be made into each nostril until the stream flows freely. This should be done every hour, or oftener if necessary. At the same time, care must be taken that none of the liquid reaches the fauces. Of otitis there is no fear. Probably the Eustachian tube is closed by catarrhal or diphtheritic swelling. He has never seen any difficulty arising from injections. A common syringe suffices; the nasal douche is much better. In neglected cases the syringe will open a closed-up nares. In such cases the tweezers

or pincers are sometimes necessary to remove the collected material. The child frequently has swelled glands—the head is thrown backwards or sidewise, or he suffers more from loss of sleep arising from obstructed nares than from the glands, and the injections give speedy and certain relief. Some children insist upon their being made.

Frequently the swelled glands have diminished in less than twenty-four hours after local treatment has been commenced. If there is an objection to this that discomfort is produced, the objection does not count. There is only one way to save a case of nasal diphtheria, and that is by disinfection and washing of the parts. What disinfectant is preferable? He avoided, in the first place, those which stain the surroundings, and those which coagulate. For that reason the various preparations of iron are not used, and also the permanganate of potassium. Carbolic acid has been frequently used by him. When there is no smell, lime-water has often been used, pure, or somewhat diluted, for its solvent effect. Internal disinfectants and antiseptics are of no effect. But, above all, attendance is necessary. He has not lost a single case in his own practice for years. He sees them early, or has them looked after, and takes care that his orders are strictly obeyed.

The panic in this city is entirely unjustifiable. It is the result, not the cause, of the newspaper discussions. With the exception of a few fatal cases, there is no disease that can be more easily or successfully managed than this, and its mortality ought to be small. A case of diphtheria, mild or severe, ought to be attended at once.

As a means of allaying the panic better than the disinfectant, he proposed that a physician should be appointed for each district of the city, to be well paid by the city, whose business should be advertised in the papers, in the schools and station-houses; and let it be understood that he will look after the throat of every pauper or tenement-house child with symptoms either of diphtheria or of pharyngitis. The result will be not only encouraging, but satisfactory. W.

[NOTE.—The writer of this communication has had occasion recently to witness in his own family the good effect of the line of treatment indicated above. Three children were affected with diphtheria,—a complication of pharyngeal and nasal. I have reason to think it is but just to say that the attending physician, Dr. E. C. Harwood, in his treatment acted upon his own original convictions. He used disinfectants, stimulants, thorough cleansing of the throat, the nasal syringe introduced posteriorly, and unremitting and constant personal attention; which remedies and means were applied early and frequently.

The result is favorable, though the patients have not entirely recovered. The youngest, a boy of about four years, exhibited nephritic, glandular, and paralytic complications. In two there is a slight difficulty of speech, and in the youngest there is not only considerable difficulty in speech, but also marked difficulty in walking. There is reason to expect a perfect recovery.—W.]

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—The girl, M. K., who was under my care last winter at the Pennsylvania Hospital for wrist-drop brought on by the use of sugar of lead as a cosmetic, and whose case I reported, together with two other cases of poisoning from the same cause, in the number of the *Times* for January 17, 1874, has recently returned to the hospital with a slight recurrence of her paralysis. At the time of her readmission she was unable to extend the middle and ring fingers of the right hand,—the hand most affected during her previous attack,—but could execute all the other movements of the hand and wrist. The paralysis must, therefore, have been limited to one muscle, the extensor sublimis digitorum; the fact that the little and ring fingers have each an extensor muscle of their own fully explaining the persistence of the power of extension in them.

The galvanic current is applied daily to the paralyzed muscle, and the iodide of potassium given in moderate doses. Under this treatment the patient is rapidly regaining the full use of her hand. She denies having applied lead in any form to her face, but the existence of a well-marked blue line along her gums makes me somewhat doubtful of the truth of her assertion.

Very respectfully, yours,

JAMES H. HUTCHINSON, M.D.

2019 WALNUT STREET, December 22, 1874.

THE FLOORS OF HOSPITAL WARDS.

AT the recent meeting of the American Public Health Association, Dr. Woodworth, of the Marine Hospital Service, in reading an abstract of his late report "On Hospitals and Hospital Construction," remarked in reference to the floors of wards that "they should be of compact wood, the joints being filled with white lead, and paraffine oil or beeswax should be used on the surface." The subject excited some discussion, and Dr. Ray said "that oiled floors would not shed dirt; all that he had ever seen had been always dull and dirty." Dr. Woodworth replied that "he meant boiled linseed oil, which afforded a hard surface."

During recent visits of surgical observation which I made among the prominent hospitals of Europe, the character of the floors of the wards was the most attractive and commendable feature in a considerable number of instances. I gave some attention to the very perfect surface of these floors, and inquired into and often saw the process by which the beautiful hardness and polish are produced and maintained. The surfaces of these floors have a polish that looks almost vitreous, and they are so hard that no impression or even dulling of the gloss is made by continued walking over them. These beautifully polished floors prevail in some of the best hospitals in London and other cities of Great Britain. The most perfect of such floors I observed in the Royal Infirmary of Manchester, the polish being equal to that of fine cabinet furniture, reflecting light brilliantly, and the surface seemed so hard and well

preserved that not a scratch or other blemish was visible.

Such floors are easily cleaned, impenetrable to moisture, and can be kept in perfection with but little and unskilled labor. If there is a single objection to them, it is that they are so slippery that there is great liability to fall on them; and I recall the guarded manner in which I walked over them.

The advantages of these enamelled floors in a hygienic view are apparent, and the appearance of the wards is rendered very attractive by them.

This hard and polished surface is produced by the simple process of occasionally *rubbing* them with a mixture of ordinary *yellow wax and turpentine*. The proportions of the combination do not seem to be very important, but enough turpentine is added to melted wax to give the mixture a very viscid consistence when cold. The rubbing is performed with woollen cloths on which a small quantity of the mixture is spread. The cloth is wrapped around a block of wood that is furnished with a long handle, so that the operator stands erect whilst at work.

This light work of polishing almost supersedes the more laborious duty of scrubbing the floors, and it can be performed by ordinary attendants or may be a light exercise for convalescent patients.

I commend the process as worthy of general adoption in the hospitals of this country.

R. J. LEVIS.

REVIEWS AND BOOK NOTICES.

ORTHOPÆDIA, OR A PRACTICAL TREATISE ON THE ABERRATIONS OF THE HUMAN FORM. By JAMES KNIGHT, M.D., Member of the Medico-Chirurgical Faculty of Maryland, etc.; Physician and Surgeon-in-Charge of the Hospital of the New York Society for the Relief of the Ruptured and Crippled, New York City, etc., etc. New York, G. P. Putnam's Sons, Twenty-third Street and Fourth Avenue, 1874.

The increased interest which has been awakened in the professional mind during the past few years in that branch of our art which relates to the relief of deformities is evidenced in two ways: first, by the establishment of special hospitals for the reception of patients thus afflicted; and secondly, by the frequent appearance of monographs and treatises on the subject. The last ten years have probably witnessed greater additions to the literature of this department of medical science than a period of three times that duration preceding. The work before us illustrates both facts, as it is the offspring of the first institution of the kind in this country, so far as we know. Fully eleven years ago we remember visiting Dr. Knight in his little domestic hospital on Second Avenue, the modest progenitor of the noble and unique building now set apart by New York munificence for the care and cure of these unfortunates, and being greatly struck with the fact developed by the cases which he was kind enough to show us, that mere position is a most important factor in the restoration of paralyzed muscles to the performance of their functions, a truth which has stood us in good stead ever since. The value of the doctor's book consists in the fact that it gives the resultant of the observation of a very large number of cases requiring mechanical treatment, under the favorable conditions of

dispensary and hospital practice, during a comparatively short period, he "having had the supervision," as he tells us in the introduction, "of 26 448 patients within the past ten years." His work seems to have been honestly and conscientiously performed, and its results have been such as to enable him to record that "seventy-five per cent. of the ordinary conditioned patients laboring under synovitic disease have been restored to self-sustaining ability, the disease having been arrested and the limbs restored to usefulness;" a sufficiently satisfactory showing. There is little that is new or startling in his conclusions. He abstains with praiseworthy modesty from the attempt to introduce any wonderful invention of his own, relying, as every practitioner will as his experience in mechanical therapeutics increases, on the modifications which the requirements of each case call for. He particularly warns the beginner against substituting the services of the instrument-maker and a fashionable apparatus for a careful personal study of the individual problems presented to him. His tendency is decidedly to conservatism and expectancy. The roller-bandage, elastic compression, careful attention to position, and strict hygiene, find much more favor in his eyes than excision, resection, gouging, and chiselling; and we are inclined to think that his figures support his views. His appliances are extremely simple, often old-fashioned; Scarpa's shoe, with very slight modification, answering all the indications in both varus and valgus, the original steel spring being preferred to india-rubber cords. In spinal caries he proposes nothing better than the old crutch support, resting on the hips. His hip splint has no other means of extension than the perineal strap. His practice in the two latter classes of diseases, viz., *exercise* in the open air, with *use* of the affected joint, protected from shock by mechanical support (as far as he accomplishes it), is decidedly in advance of his pathology, *struma*. The importance of tenotomy in talipes and the paralytic distortions, as a preliminary to further mechanical treatment, is strongly urged, and the directions for the performance of the operation on the different tendons are careful, explicit, and judicious.

As a literary effort the work does not commend itself to us. With a certain attempt at system, there is much confusion in the general arrangement. There is a constant attempt to bolster up faulty rhetoric, and even bad grammar, by bombastic phraseology. For instance (p. 10), "1. That of an arrestation of development, emanating from the nervous centres; or, as some believe the blood-vessels to precede the nerves, by their impairment affecting the peripheral appendages of the primary nucleus, and determining the normal or abnormal development of the foetus." *Arrestation* "is good." Again: "4. That unfavorable positions of the foetus *in utero*, influenced by the spherical boundary of the latter, is a primary cause of distortion, more especially of the extremities." On page 283 he recommends a "mucilage" made of "bread having been baked forty-eight hours," and says of milk-punch that "experience has rendered it objectionable in some cases."

Nor is he happier in his use of foreign tongues or dead languages. Witness page 41, "In the foot of the bear, the malleola are," etc. Page 282, "a proper régime." Page 9, "enciente." Page 198, "treatment of genu extrorsum." The chapter on electricity is a crude rehash, apparently introduced as a puff to the "Galvano-Faradic Manufacturing Company." The cuts which this company has furnished are the best in the volume, the illustrations generally being faulty in design and rough in execution. The book, as a whole, while containing many valuable practical hints, will not help to elevate the standard of American medical literature.

B. L.

A SKETCH OF THE EARLY HISTORY OF PRACTICAL ANATOMY. By WILLIAM W. KEEN, M.D. Philadelphia, J. B. Lippincott & Co., 1874. Pp. 43.

This brochure, the subject of a lecture delivered before the class of 1874-5 in the Philadelphia School of Anatomy, is a republication of the same matter presented to the author's class of pupils of the class of 1870. The edition published by the latter was soon exhausted, and those who had applied too late for copies will now be glad to hear of its reappearance in a neater and more permanent shape.

As a rule, we hold essays on the history of medicine to be uncommonly stupid affairs, lifeless and limp, and savoring of the encyclopædia. The reader will find this essay, on the other hand, a very entertaining account of the history of that branch of anatomical science to which the author has so successfully devoted his energies.

We would suggest as a theme in the same line of research the History of the Philadelphia School of Anatomy, and hope Dr. Keen will place on record the varying fortunes of this famous school, which has educated hundreds of this and the preceding generation of physicians, and developed the powers of many of our most brilliant lecturers. The present time would be an opportune one to present the profession with such a chronicle, and it is especially fitting that Dr. Keen should undertake the task before the buildings are demolished to make way for the new post-office.

STUDIES IN THE FACIAL REGION. By HARRISON ALLEN, M.D. 56 Wood-cuts. 8vo, pp. 117. J. B. Lippincott & Co., 1875. For sale by S. S. White, Twelfth and Chestnut Streets.

The author states in his preface that these are mostly jottings from his lectures as Professor of Anatomy in the Philadelphia Dental College. The subject is treated topographically, in ten divisions, beginning with the Region of Expression. As a whole, the book at once arrests our attention by its judicious blending of philosophical and descriptive anatomy with their practical applications in explaining the phenomena of disease. Nor must it be presumed that the book is intended solely for dentists. While everything of interest to them is retained, there is not a page which is not of the greatest value to the practical physician or surgeon. The artist will find in the chapter on expression much that is valuable, and the comparative anatomist will receive with the greatest pleasure the contribution to the study of the development and the nomenclature of the teeth in the last few pages,—a chapter as valuable as it is novel. In the section on the localization of diseased action we recognize the same principles as in the author's previous valuable paper in the *American Journal* in 1870. A remarkable illustration of this we saw during the war, in which, from excessive salivation, the whole of the right superior maxilla, with the *premaxilla*, necrosed and exfoliated. The case is described (but not accurately) and the bone figured on p. 53 of the Army Museum Catalogue. Rarely do we meet with so good a little book as this, and we hope it may have a hearty reception from the profession.

W. K.

THE MEDICAL USE OF ALCOHOL AND STIMULANTS FOR WOMEN. By JAMES EDMUNDS, M.D. New York, National Temperance Society and Publication House.

This little brochure consists of reports of various addresses delivered in this country by Dr. Edmunds, member of the Royal College of Physicians, London. It contains little or nothing that is at once novel and true, but much that is novel and false. Thus, on page 51 we are told "that the babies of the present generation are never sober from the earliest period of their

existence until they have been weaned." We are assured that this assertion "is a simple fact." All we have to say in comment is that as the human conscience may be annihilated by repeated crime, so does it seem to us the human intellect may lose the divine power of distinguishing truth from falsehood by being employed upon the work of a partisan temperance lecturer. We sincerely hope Dr. Edmunds's book may have some influence in arresting intemperance, but certainly cannot think our readers will ever want to peruse more than one page of it.

THE DISEASES OF THE STOMACH. By WILSON FOX, M.D. H. C. Lea, Philadelphia, 1875.

This is a reprint of the third English edition of the *Diagnosis and Treatment of the Varieties of Dyspepsia*, a not absolutely fresh work, since the author's preface is dated October, 1872. This "third edition" was really in a considerable degree a new book, since, besides minor contributions, articles on ulcer and cancer of the stomach were added. These chapters, while containing nothing that is new, are well-written résumés of our knowledge upon the diseases of which they severally treat, and contain an elaborate bibliography of the subject. Dr. Fox seems to be ignorant of the great value of turpentine in some cases of chronic ulcer not attended by hemorrhage, and we think underestimates the value of nitrate of silver.

GLEANINGS FROM OUR EXCHANGES.

KOUMISS (*The Peninsular Journal*, December, 1874).—Mr. E. C. Saunders quotes Dr. Jagielski, of Berlin, as asserting that the action of the several constituents of koumiss may shortly be specified as follows:

The *lactic acid* excites the digestive powers, diminishes the temperature and the frequency of the pulse, and regulates the mucous secretion. It has an additional specific action in certain cases, as, for instance, in diabetes.

The *casein*, *albumen*, and *fat* restore the plastic and heat-giving materials of the body, and promote assimilation of its associate constituents.

The *lactose* increases the weight of the body and gives heat.

The *alcohol* produces sleep, diminishes heat, and forms fat.

The *carbonic acid* allays nausea, calms gastric irritation, augments diuresis, increases the energy of the heart's impulse, and diminishes the frequency of the heart's contractions.

CUTANEOUS ERUPTIONS SYMPTOMATIC OF RHEUMATISM AND GOUT (*The Boston Medical and Surgical Journal*, December 3, 1874).—Dr. James C. White quotes Professor Profeta, of Palermo, who describes as follows a peculiar set of cutaneous lesions which are produced by and are diagnostic of the rheumatic diathesis:

1. The arthritides are seated sometimes upon parts of the body which are exposed, sometimes upon those which are rich in sweat-glands and hair-follicles, sometimes upon the skin which covers the joints. They are always circumscribed, and if by chance they spread, they never become general.

2. They never appear all at once, but are always developed by successive outbreaks.

3. They are asymmetrical, inasmuch as they never affect two corresponding regions, and, when occurring upon both sides of the body, their abundance and distribution are not the same.

4. The eruption appears in groups, which do not extend, and which never occupy any considerable surfaces.

5. The affected skin is generally of the color of red wine or a raspberry, and small hemorrhagic spots are often seen in the midst of the eruptions.

6. The efflorescences are polymorphic.

7. They are essentially dry, exhibiting no tendency to suppuration or to serous exudation.

8. The sensation connected with them is not decidedly pruriginous; it is more prickling or burning.

9. The first outbreak lasts quite a long time; but as they are repeated they disappear more rapidly, and at last have only an ephemeral duration.

10. The arthritides almost always relapse.

RUPTURE OF THE UTERUS—NEW SYMPTOM (*Virginia Medical Monthly*, December, 1874).—Dr. Robert J. Preston reports the case of a multipara, æt. 26, who was troubled during her third labor with severe flying pains in the back. At the second examination which was made, a small tumor, of a cushion-like, soft feel, was discovered just below the utero-vaginal junction, occupying the right latero-posterior aspect of the vagina. Some suspicion of pelvic hæmatocele was felt at the time; but, the swelling being insufficient to interfere with the progress of labor, the pelvis large and capacious, and the previous labors having been short and easy, no special attention was given to it.

Four hours later, this swelling had disappeared, but, as the pains were infrequent and feeble and the head was advancing very slowly, ergot was administered. A few hours later the patient gave a sudden cry, and was found to have all the most alarming symptoms of shock, and it was then recognized that the uterus was ruptured. She died in a short time. In cases where the rupture is a small one, and contractions do not immediately cease, the diagnosis becomes very difficult. It is in these cases, which, unusual as they may seem, are nevertheless of pretty frequent occurrence, that this new symptom—this sub-peritoneal tumor appearing in the hypogastric region, in the groin, or in the vagina—becomes unquestionably one of great value, as indicative of this initiatory lesion or perforation, and as premonitory of an impending crisis more terrible; but which may be averted by the immediate and timely extraction of the child and its appendages. In the case above reported, the swelling in the vagina, discovered some eight hours before the fatal issue, was undoubtedly a tumor of the character described,—a sub-peritoneal effusion from slight rupture or perforation of the uterine tissue; and had its significance been appreciated at that time, and the immediate extraction of the fetus and its appendages been procured, the final issue might probably have been different. It is useless to say that, under the circumstances described, no ergot, even tentatively, should have been given.

SCALD OF THE GLOTTIS (*The Dublin Journal of Medical Science*, October, 1874).—Dr. Corley reports the case of a child, two years and ten months old, who tried to drink out of a kettle containing boiling water, and seemed scalded at the time, but soon recovered, and went to sleep quietly. About three hours afterwards he awoke with great difficulty of respiration, and was taken to a hospital. Here he was at once placed in a room where an equable and moist temperature was maintained. The dyspnœa occurred in spasms, which grew more and more frequent, and during their continuance there was great cyanosis. A grain of calomel with one-sixteenth of a grain of tartar-emetic was exhibited every hour, and half a drachm of strong mercurial ointment was rubbed into the groins and axillæ at the same intervals. Six leeches were applied, and hot sponges were kept constantly on the throat. No

important change took place for about six hours, except a gradual diminution in the frequency of the pulse, which necessitated the withdrawal of the tartar-emetic and the administration of the calomel at shorter intervals. The respiration grew more rapid, crepitating râles could be heard down to the bases of both lungs posteriorly, whilst percussion over the same parts elicited marked dulness. The case was judged to be too far gone for operation, and the child's mother was informed that there was no hope. Just four hours later, green stools appeared, and coincidentally slight symptoms of improvement became manifest. The case resulted in entire recovery. The active treatment, which extended over seventeen hours, may be thus summed up: Twenty-four grains of calomel, six drachms of mercurial ointment, three-fourths of a grain of tartar-emetic, and the application of six leeches.

INHALATION IN A CASE OF CASTS OF THE BRONCHIAL TUBES (*The Lancet*, November 7, 1874).—Dr. Edwin Payne reports the case of a youth of sixteen, who was much troubled by coughing up frequently, indeed almost daily, a firm white material, sometimes in considerable quantities. This, upon examination, presented the appearance of regularly-formed casts of the bronchial ramifications, from bronchi of the third and fourth order, consisting of tree-like, repeatedly forked coagula of a white color. Upon examining the chest the sounds were healthy, with the exception of some sibilant rhonchus at the infrascapular region of the left side. He had brought up these casts during a period of two years. The only history of previous illness was that as a child he had had diphtheria.

For the space of two months he was under treatment, and used an inhalation of creasote and tincture of iodine, five minims to ten minims of each in a pint of steaming water twice or three times a day; at the same time he took some dilute nitric acid and bark twice a day. The progress of the case was, that the casts gradually diminished, and concurrently the amount of the sibilant rhonchus diminished also, until at the end of the two months he was free from his trouble, and upon reporting on two or three occasions, the last of which was after the lapse of three months, he had had no return.

FATAL HEMORRHAGE FROM A UTERINE SINUS (*The Lancet*, Nov. 28, 1874).—M. Depaul, the eminent obstetrician of Paris, lately mentioned a peculiar case before the Surgical Society. In 1869 he had attended a woman in labor affected with the rickets, and had been obliged to break up the head. Quite lately she again fell in the family way, and M. Depaul determined to excite premature labor. The antero-posterior diameter was three inches and a half. Tarnier's tube was introduced into the uterus, and gave rise to some pains, but the tube slipped out twenty-four hours afterwards. The author was getting ready with the prepared sponge, when the patient was seized with violent pain in the upper part of the abdomen on getting out of bed. She grew very pale, and died in a few hours. The Cæsarian operation was performed, but the fetus was dead. A perforation was found at the posterior and superior portion of the uterus, and around the hole were noticed large subperitoneal sinuses. The opening corresponded with the placenta, which, on being detected, was found to be more adherent than usual. In 1869 the placenta had been removed by the hand of the accoucheur passed into the uterus. The uterine walls were very thin around the perforation, and had undergone fatty degeneration. No blood was found in the womb, but three pounds of it were taken from the abdominal cavity. A sinus was observed, which looked worn out and severed just by the perforation. Through this the blood had escaped, and the continual loss had killed her in three hours.

MISCELLANY.

NEW PROCEDURE IN SKIN-GRAFTING.—In order to avoid the difficulty of borrowing numerous grafts from the individual on whom they are to be applied, Dr. B. Anger, a Parisian surgeon, has had the idea of taking them from amputated limbs. He has been quite successful with grafts of all kinds,—epidermic, dermo-epidermic, including the whole skin, and taken from the mucous membrane of the foreskin. In all the cases the graft was made whilst the temperature of the amputated parts was still high. In two cases the patients had been placed near each other, so as not to lose any time in grafting.—*London Lancet*.

THE death of Mr. John B. Foster, assistant to Sir Henry Thompson, recently occurred in London. It was caused by an explosion of gas which took place as he was lighting a large chandelier.

A MODEST EDITOR.—“We claim, as the special excellence of *The Clinic*, that it contains more readable matter than any paper published in this country.”—*The Clinic*. The *Philadelphia Medical Times* publishes about twice as much matter yearly as the *Clinic*: of the quality we leave the public to judge.

PROFESSOR AUSTIN FLINT, JR., has been appointed Surgeon-General of the State of New York, on the Staff of Governor Tilden, newly elected.

NOTES AND QUERIES.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

MESSRS. EDITORS,—Prof. Erichsen may well be pardoned for asserting that he knows of “no special hospitals in any of the great American cities,” when our own people appear deficient in such knowledge, or, if aware of their existence, choose to ignore them. The “Howard Hospital and Infirmary for Incurables” is such an institution, and I believe the only one in Philadelphia which makes *specialties* its sole prominent feature. It has been in “active and very flourishing” existence for over twenty years, having been chartered by the Legislature in May, 1853.

Its efficiency and very satisfactory results to both physician and patient, the annual reports of its Board of Managers abundantly prove. It has a staff of ten physicians and surgeons, besides two resident or, as the phrase is, *interne* physicians, and employs a matron and steward. The specialties are classified in the following order: diseases of the digestive organs, diseases of the chest and throat, diseases of females, obstetrics, diseases of the brain and nervous system, fevers, vesico-renal affections, diseases of the eye and ear, diseases of the skin, surgery. We have thus nine divisions, to each one of which a physician exclusively devotes himself, except in the department of surgery, which comprises two.

The institution is controlled by a Board of Managers, consisting of twenty-four gentlemen, among the most enlightened and benevolent of the citizens of Philadelphia. Quiet and unpretentious, but thorough in its direction and appointments, it has afforded relief to thousands of the worthy poor and suffering in our midst, and has yielded, to the physicians whose time and talents have been devoted to its laudable success, a vast and rich fund of information and experience, with the consciousness of well-directed professional and philanthropic aims. T.

SHADY-SIDE, MONTGOMERY CO., Dec. 30, 1874.

KANSAS CITY, Mo., Dec. 19, 1874.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

On the night of the 11th of this month, the Professor of Surgery (Dr. Taylor) in the College of Physicians and Surgeons of this place rushed into

my room and asked me if I would not attend Mrs. A., just about to be confined, and remarked, “She has sent for me to come.” So, in compliance with the Professor’s wish, I at once started. On my arrival, I found a large German woman, apparently inactive labor. I immediately made an examination; waited a few minutes for a pain, but no pain came. On placing my hand upon the abdomen, I was surprised to find very little tumefaction. On questioning the woman, I found she had been married twice, had borne two children by her first husband; none by her second; and had been married to him only twelve months. She also remarked, “I have never missed a month.” “Then why do you think you are pregnant?” “Because I am eight inches larger around the waist than when I married, and I am so large I have been ashamed to be seen on the street for a month past, and often I have felt the movement of the child.” Not believing her to be pregnant (notwithstanding the baby-clothes, etc., she had lying around the room), I gave her one-fourth grain of morphia, and left. The next day Professor Taylor and myself examined the woman thoroughly, and found the os normal; but in passing the sound the interior of the womb was quite sensitive, and a slight discharge of blood followed the withdrawal, but no child, no ovarian trouble, no fibroid, no polypus, and, in short, nothing that would point to any abnormal trouble whatever. It seems that since the woman’s last marriage she has gained some thirty-five or forty pounds of flesh, and, her abdominal muscles being very much relaxed, the whole viscera has gravitated towards the pelvis, giving much the appearance of a pregnant woman. The extra pain experienced at the time was occasioned by the menstrual discharge, which was just appearing.

E. R. LEWIS.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—Will you oblige me by inserting the following letter in your journal?

W. S. KING.

“PHILADELPHIA, Dec. 29, 1874.

“DR. W. S. KING, U.S.A.:

“DEAR SIR,—Accompanying this you will find samples of some preparations which have been originated and made by me. Among others I would call your attention to solutions of morphia and veratria in chloral and glycerin, on account of their adaptation to the requirements of the physician as topical applications in neuralgia and rheumatism, believing that such compounds would afford relief on account of their solubility and diffusiveness. For a full description of the method employed by me for making them and other combinations of the alkaloids with chloral as a solvent, allow me to refer you to the article written by me and published in the December number of the *Journal of Pharmacy*, 1874.

“During the prevalence of smallpox in 1871 and 1872, I had frequently been requested by my friends to prepare a cologne possessing disinfecting properties. I found in preparing such an article that upon mixing hydrate of chloral and carbolic acid the disagreeable smell of the latter was almost entirely removed, and upon adding these to spirits of lavender or ordinary cologne-water a not unpleasant odorous volatile solution resulted. This, used with an atomizer, readily saturated an ordinary-sized apartment with the vapor of these most valuable antiseptics. The idea of using chloral as a disinfectant I believe occurred to me in consequence of the fact that during those years on several occasions you spoke to me of having found that that substance was a most powerful antiseptic, stating that you had used it as such with the most satisfactory results in the preservation of anatomical specimens.

“I think, then, that you will perhaps look favorably upon this peculiar disinfectant, a vial of which you will find in the package. Hoping that I am not trespassing too much upon your time, and that your health has improved,

“I am yours respectfully,

“ROBERT F. FAIRTHORNE.”

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JANUARY 5, 1875, TO JANUARY 11, 1875, INCLUSIVE.

KINSMAN, J. H., ASSISTANT-SURGEON.—Assigned to duty at Fort Abraham Lincoln, Dakota Territory. S. O. 284, Department of Dakota, December 30, 1874.

ROSE, GEORGE S., ASSISTANT-SURGEON.—When relieved by Assistant-Surgeon Loring, to comply with War Department Orders No. 233, c.s. S. O. 111, Department of Arizona, December 21, 1874.

LORING, L. V., ASSISTANT-SURGEON.—Assigned to duty at Fort Yuma, California. S. O. 111, c.s., Department of Arizona.

WIGGIN, A. W., ASSISTANT-SURGEON.—Relieved from duty in the Department of the Columbia, to report in person to the President of the Army Medical Board, New York City, for examination for promotion, and, upon its completion, by letter to the Surgeon-General. S. O. 3, A. G. O., January 6, 1875.

SATURDAY, JANUARY 23, 1875.

ORIGINAL LECTURES.

CLINICAL LECTURE

ON THE INDUCTION OF PREMATURE LABOR.

(Abstract of a Clinical Lecture delivered at the Allgemeines Krankenhaus, Vienna.)

BY PROF. CARL BRAUN.

Reported by G. WILDS LINN, M.D.

GENTLEMEN,—I propose calling your attention to-day to the various methods made use of in the operation for the induction of premature labor. The manner of performing an operation so often required at the hands of the obstetrician, and upon which is dependent so much of good or of evil to mother and child, is, as you may suppose, of the greatest importance. It has taxed the ingenuity of the accoucheur for a century, and there yet remains in the mind of the profession much doubt and speculation upon the subject. There are those, it is true, who, by a complication of modern contrivances, claim to achieve brilliant successes, and to make this one of the easiest operations we have to perform. I hold in highest estimation the man of practical mind who makes use of few measures and those the most simple, while, on the contrary, the man with theoretical ideas and a multiplication of means is least to be trusted.

Without risk of incurring the charge of egotism, I think I can say I have had as many opportunities of ascertaining the relative values of the various methods used as any other man living,—certainly as many as any man in Germany; and therefore when I speak upon this subject I assume the right of speaking with some authority.

In considering the methods employed, or any particular method, it is first absolutely necessary that we bear in mind the character of the organ with which we have to do. Suffice it to say that the pregnant uterus and the non-pregnant uterus are two very different organs, and the treatment of these must be correspondingly different. He who thinks otherwise has had but little experience, and errs very much. The uterus of the pregnant woman is an exceedingly sensitive organ, and in all our operations upon it the fewer manipulations we make consistent with the necessities of the case the better.

The old method which was employed when the induction of premature labor was first sanctioned by the profession was the simple opening of the amniotic sac. This plan was for a long period practised, and with very good results. In time, however, it was affirmed that this early draining away of the amniotic fluid was inconsistent with the gradual dilatation of the cervix, and, hence, with the normal progress of labor. Then it was suggested to open the sac higher up at a distance from the os; and this method is still used by some who claim to have thereby good results. In reality this makes no dif-

ference in the progress of the case, as the rent made will proceed to the cervix so soon as labor-pains are developed.

The old writers, who entertained different ideas from those we hold concerning the length of the cervix in the latter months of gestation, deviated in time from the original simple plan. The first change made was in the introduction of the trocar with stilette. The danger in using this is at once apparent when we remember that very frequently the cervix lies horizontally in the vagina, so that the point of the instrument, if not carefully introduced, will pass through the posterior wall of the cervix. If force be used, it may not only pass through the wall, but, entering the peritoneal cavity, be made to enter the posterior wall of the uterus, and give exit to the amniotic fluid through the false passage so formed. In such a case, which is far from being impossible, the physician is not at the time aware of the injury he has done, and probably will not be until the death of his patient from parametritis or peritonitis reveals it in a post-mortem examination.

The mechanical dilatation of the cervix by the various speculæ devised for that purpose as a means of provoking labor are entirely disapproved of by me. Some of these speculæ I here show you. These all bear an antediluvian appearance. Some such instruments have been found among the ruins of Pompeii, and, though strongly advocated by some such men as Busch and Krause, are found deficient on trial.

The use of sponge tents has become very popular in late years in this operation. Simpson, who designed the tent, devised it for the non-pregnant and not for the pregnant uterus. That its use here is often productive of most serious if not fatal results cannot be questioned. It is often productive of parametritis, and pyæmic symptoms arising from the absorption of the foul discharges to which it gives rise are of no infrequent occurrence. That it is uncertain as to time is also true. I have in many cases used it for days before I have succeeded in provoking active labor-pains. Laminaria tents have not been found more efficient than sponge tents, and, like them, will produce dangerous complications. Any foreign body which must so long remain in the cervix is dangerous.

The use of the catheter or flexible bougie I will not allow in my wards under any consideration. Its use has been highly lauded by some, and yet I am sure that here, as is too often the case, the favorable cases are reported, while those that are fatal are never heard from. Like the tent, it is also uncertain as regards time, and I have often used it for many days before delivery was accomplished. It cannot be employed with my sanction, and he who uses it does so on his own responsibility.

The use of injections into the uterine cavity, according to the method of Cohen of Hamburg, is dangerous. Many patients die from such treatment. Injections of water, either simple or medicated, should not be allowed under any circumstances, and would not be allowed by any one who understands the inextensible character of the uterine tissues.

The use of cold water under such circumstances is barbarous in the extreme, always giving rise to the most intense pain. I entirely discountenance the use of intra-uterine injections, and hope that no student of mine will ever permit himself to make use of them to induce labor.

Vaginal injection, or the douche, according to the method of Kiwisch, is also most dangerous, and he who thinks differently has had but little experience. It does not act surely or quickly, and an inflammatory process very often results. Death, too, is not an infrequent occurrence from its use. I do not wish to entertain an unfounded prejudice, nor would I express myself so positively if I had not good reasons for doing so. A man, too, should be especially careful in opposing a method which is so popular. The manner in which the douche is applied makes but little difference. Great pain often follows its use,—a fact abundantly established by the histories of cases we have had in this hospital. I am not alone, however, in entertaining this opinion, for very many others who have tested this method coincide with me in this opinion. The danger in the use of the douche has not been found very great where the neck of the uterus is conical, the os being small; but where we have reversed conditions—a large cervix with the os somewhat dilated—the danger is proportionately increased. Hence the very probable presumption that the difficulty is produced by the entrance of the fluid into the uterine cavity. In this way also air may find a passage into the uterus, and death result from its transmission to the heart through the venous system. That fluid may pass through the Fallopian tubes into the peritoneal cavity is very possible; but I cannot so readily believe that the danger to be apprehended from this is great.

The tampon used by some is not to be recommended. It finds a much more proper place in placenta prævia, for it can be there used to much better advantage than in the induction of labor. Its action in the latter case is very slow and uncertain.

For many years elastic bladders dilated by air were used by the French, and more recently they have been extensively employed in England for the dilatation of the cervix; but they have failed to give satisfaction.

The injection of carbonic acid after the method of Scanzoni must be placed upon the same plane with the injection of water. Patients will die from its use, with the same symptoms and having the same post-mortem appearances as if they had suffered from the inhalation of the gas.

Suction of the mammæ for the purpose of inducing labor is entirely untrustworthy as generally practised. If persevered in until the desired result were effected, mastitis would certainly be a consequence.

Faradization as signally fails as suction of the mammæ, and cannot be relied upon. For many years I have had abundant opportunities to practise all these different methods, and now have an idea of what is right. Under no circumstances whatever will I allow myself further to experiment. The plan which I here pursue I have found upon a

long and faithful trial to give better results than any other. This is nothing more than the practice of the original method, consisting in the employment of a pointed quill, or, what will answer the same purpose, a steel pen. This method, besides having the advantage of simplicity, is always applicable, as the instrument is ever at hand. The point of the quill is placed upon the palmar surface of the index-finger, which is then passed up to or through the cervix, and the membrane punctured. An improvement on this plan consists in making an opening in the side of the quill through which a sound can be introduced. The point of the quill is then brought into close apposition with the body of the sound. The latter is then passed through the cervix, the quill being kept in position, and when the desired distance is reached the sound is withdrawn, leaving the quill behind, and the puncture can be made. In this manner we overcome the difficulty of passing the projecting angle of the posterior wall of the cervix.

By this method no damage can result, and a long narrow cervix can be readily passed. As the amniotic fluid drains away, pains are induced, the head passes down, and in twelve hours delivery can generally be accomplished.

ORIGINAL COMMUNICATIONS.

OBSERVATIONS ON FLUORESCENCE,

CHIEFLY WITH REFERENCE TO THE ALKALOIDS OF CINCHONA.

BY CHARLES K. MILLS, M.D.,

Assistant-Physician to the Episcopal Hospital; Chief of the Dispensary for Nervous Diseases, University Hospital.

THE spectrum of a solar or other similar beam of light consists, first, of visible rays, embracing the primary colors of Newton; second, of ultra-violet, invisible rays, discovered by Ritter; and, third, ultra-red, invisible rays, discovered by Sir William Herschel. Each division and each color represents a certain degree of refrangibility. Fluorescence is a term applied to the lowering of this refrangibility, and the resulting luminous phenomenon. The fluorescent effect may begin in any portion of the spectrum, but the change is always downward; the length of the light-wave is increased, and its velocity of undulation diminished. In calorescence, which is sometimes spoken of as negative fluorescence, refrangibility is raised; but of this subject, which has been investigated by Akin, Tyndall, Bohn, and others, I do not propose in the present article especially to treat.

Each spectral division and color also means so many vibrations: four hundred and fifty-one millions of millions of oscillations per second, for example, produce the impression of red; seven hundred and eighty-nine millions of millions, that of violet; while above the violet the vibrations are even greater than this number. Fluorescent substances *slow* these vibrations. When waves of the luminiferous ether, visual or non-visual, strike the molecules of such a substance, they cause vibrations

among these molecules, but the vibrations are of *slower period* than those of the exciting waves. While some bodies transmit incident light, and others absorb it, fluorescent substances convert it into light of another kind. Slowing of vibrations, and lowering of refrangibility, are, in effect, the same phenomenon.

I will here cite only a single instance of fluorescence. A solution of sulphate of quinia is colorless when viewed by transmitted light; but when placed in a glass, and looked at from certain angles, it presents a beautiful celestial-blue color, which is due to fluorescence. The rays which produce this blueness are not the ordinary blue rays, but they are the ultra-violet or Ritteric rays, which have been rendered visible by the intermediation of the solution of quinine.

Sir John Herschel (Phil. Trans., 1845) first called attention to this phenomenon, which he attributed to *epipolic* or *superficial dispersion* of the incident light. Sir David Brewster (Edin. Trans., vol. xvi., and Phil. Mag., June, 1848) examined a large number of substances for the same property, using a lens to condense the beams of the sun. He considered the peculiar appearance to be due to *internal dispersion*. The name of Prof. G. G. Stokes is, however, pre-eminent in the history of fluorescence (Phil. Trans., 1852, 1853, 1862). His great discovery, published in 1852, was that the phenomenon hitherto ascribed to epipolic or to internal dispersion was in reality due to a change of the refrangibility of light. In 1853 he described a method of observation by the use of absorbing media, and in 1863 he made public some researches on the long spectrum of the electric light.

W. A. Miller (Phil. Trans., 1862) has investigated many of the elongated spectra obtained when secondary sparks from an induction coil are passed between metals.

Dr. Henry Bence Jones (Proc. of Royal Soc., April, 1866, and Lectures upon the Application of Chemistry and Mechanics to Pathology and Therapeutics, London, 1867) has published some researches of great interest, "On the Existence in the Textures of Animals of a Fluorescent Substance closely resembling Quinine," which supposed substance he called "Animal Quinoidine." Drs. Jones and Dupré had previously determined the rate of passage of lithia, and other mineral matters, into and out of the body (Proc. of Royal Soc., February, 1865). Before the investigations of Jones and Dupré, a few researches into the fluorescence of the media of the eye had been made by Brücke, Helmholtz, Regnaud, Setchenow, and Donders.

From Prof. H. C. Wood's "Treatise on Therapeutics," p. 68, I learn that Dr. Chalvet (*Schmidt's Jahrbücher*, Bd. cxli. p. 152, from *Gazette Hebdomadaire*, 2d series, t. v., 1868) has found that this fluorescent body, investigated by Dr. Jones, exists in various foods, and even in wine, and is therefore probably not of animal but of vegetable origin.*

Drs. Rhoads and Pepper (Penna. Hosp. Rep., 1868) have published a brief but interesting contribution on the Fluorescence of the Tissues. The blood of malarial patients, tested by them, yielded a fluorescence considerably less than its normal degree, which, after the administration of the sulphate of cinchonia, was found to be notably increased. In two cases, which died while under observation, the fluorescence of the spleen and liver was determined to be much above the healthy standard.†

From first to last in the history of fluorescence, the sulphate of quinia has been one of the chief subjects both of theory and of experiment. Herschel's experiments were mostly made with a quiniferous solution. He examined a specimen of very pure cinchonine, but could not discover that it possessed in the smallest appreciable degree the property of epipolic dispersion, or fluorescence. Imperfect methods of observation will probably account for this result. Solution of the sulphate of quinia was also one of the principal fluids employed by Brewster, and Stokes has devoted large space to the consideration of the same substance, and other salts of quinia. With a spark from a Ruhmkorff coil, Bence Jones found that sulphate of quinia gave slight fluorescence with $\frac{1}{850000}$ of a grain; feeble fluorescence with $\frac{1}{330000}$ of a grain; and distinct fluorescence with $\frac{1}{250000}$ of a grain. The alkaloids of cinchona, other than quinia, have received but little attention from investigators.

Drs. Rhoads and Pepper used the sulphate of cinchonia instead of the sulphate of quinia in their experiments. Deeming it advisable to ascertain approximately the relative degrees of fluorescence possessed by solutions of these two salts, they were tested for that purpose, with the following results: A solution of sulphate of quinia, obtained by adding ten grains of the salt to a litre of distilled water, without the presence of any sulphuric acid, and allowing the mixture to stand, with frequent agitation, for many hours, was tested, and yielded an intense fluorescence. The addition of sulphuric acid to this solution increased its fluorescence to a small degree only. A solution of sulphate of cinchonia, twenty grains to the litre, was found to possess positive fluorescence; though very much less intense than that of the quinia solution, which was of but one-half its strength.

Recently I have made some fluorescent investigations of the alkaloids and salts of cinchona, partic-

* Quinia and its salts have the remarkable property of converting rays of heat into light, or, in other words, of rendering visible the ordinary invisible rays. The first half of this sentence conveys a wrong impression. The invisible heat-rays, so called, are the ultra-red or Herschelic rays at the least refrangible extremity of the spectrum. In order to convert these into light-rays, it is necessary to raise instead of to lower refrangibility, and this process of elevation constitutes the phenomenon of calorescence, and not fluorescence, to which Dr. Wood is referring. The invisible rays which are rendered visible by quinia are the ultra-violet or Ritteric rays.

† Prof. Henry Morton has made some valuable discoveries in fluorescence. His researches may be found in the Journal of the Franklin Institute, American Chemist, Chemical News, and Philosophical Magazine, since 1870. Other names more or less prominent in the history of the subject are Becquerel, Werther, Böttger, Osann, Foucault, Müller, Robinson, Pierre, Parnell, and Hagenbach; whose investigations may be seen in *Annales de Chimie et de Physique*, *Comptes-Rendus*, *Poggendorff's Annalen*, and *Philosophical Magazine*. For general expositions of the topic and for pertinent optical principles, the works of Tyndall and Schellen, the Chemistry of Graham and of Miller, and the Treatises on Natural Philosophy of Ganot, Silliman, or Deschanel, might be consulted.

* In passing, I may take occasion to note an important mistake in regard to the subject of fluorescence made on the same page of Wood's "Therapeutics" as that from which I have just quoted. Dr. Wood says,

ularly of the sulphates of quinia, quinidia, cinchonidia, and cinchonina. I have never seen any account of the examination for fluorescence of the sulphate of quinidia or the sulphate of cinchonidia, or any of the pure alkaloids, excepting cinchonine.

Stokes, Morton, and others describe various methods of determining fluorescence, in the papers to which I have called attention, and to which I would refer the reader. In these methods the principal elements are reflectors and lenses to condense the light, colored glasses or solutions, such, for instance, as a strong solution of ammonio-cupric sulphate, for cutting off all but the highly refrangible rays, and prisms for analyzing either the incident or the dispersed beam, or both. I have generally used either the simple plans of Herschel and Brewster, or what might be termed the Geissler-tube method, not having apparatus for other methods at my command.

Herschel allowed sunlight to fall upon the substances under examination, which, if liquid, were placed in glass vessels, as test-tubes. Brewster, by means of convex lenses, condensed the light. Vessels holding solutions may be set upon some dark material, and they may be surrounded with black paper which has an opening in it on the side towards the light, the liquid in this case being observed from above, in a direction nearly parallel to the surface. Lenses of different foci and diameters may be used, and rough comparisons made by placing different solutions side by side, or by causing them to pass rapidly one after another before the eye.

In the Geissler-tube method, a Ruhmkorff coil and double tubes are employed. These tubes consist of an inner chamber, through which the electric spark is passed, and which contains air, or some vapor or gas, in a highly rarefied condition. Surrounding this inner tube is another for holding the solution to be examined. For comparative determinations, two or more similar tubes may be introduced into the same electrical circuit; or a U-shaped tube may be used, as described by Rhoads and Pepper.

The chief preparations of cinchona which I have examined for fluorescence are—1. Acidulated solutions of each of the four sulphates,—of quinia, quinidia, cinchonidia, and cinchonina,—of the following strengths: *a*, 20 grains to the fluidounce of distilled water; *b*, 10 grains; *c*, 1 grain; *d*, $\frac{1}{180}$ of a grain. 2. Solutions or mixtures, one grain to the fluidounce of distilled water,—made without the addition of any acid, by frequent agitations during many days,—of the four sulphates, and also of the pure alkaloids, quinia, quinidia, cinchonidia, and cinchonina. In preparing the acidulated solutions, I endeavored to use the least amount of chemically pure sulphuric acid that would cause the salts to dissolve readily and thoroughly: for example, ten grains of sulphate of quinia required about five drops of acid; ten grains of sulphate of quinidia, about three drops; ten grains of sulphate of cinchonidia, about three drops; ten grains of sulphate of cinchonina, about four drops.

Each of the acidulated solutions of the four sul-

phates exhibited in a marked degree the property of fluorescence. The cinchonina salt gave the least fluorescent effect. The distinctions between the other sulphates were less positive. The order of fluorescence, from the most to the least intensity, appeared to be—1, sulphate of quinidia; 2, sulphate of quinia; 3, sulphate of cinchonidia; 4, sulphate of cinchonina. I was sometimes a little in doubt as to whether the quinia or quinidia salt gave the more decided fluorescence. Owing to the possibility of the eye being deceived in such experiments, and the fact that an extremely minute amount of a substance is capable of materially changing its degree of fluorescence, it is probable that prismatic or spectroscopic determinations in which the fluorescence is measured by fixed lines in the spectrum can alone be absolutely depended upon by investigators. The determination of fluorescence, however, in substances which have not before been examined for this property, and the ascertaining of the fact of the existence of differences in the degrees of fluorescence possessed by alkaloids and salts of the same article, are themselves matters of importance, especially from the point of view of some theories which will be advanced hereafter.

The one-grain solutions or mixtures of the sulphates, made without acid, gave distinct fluorescence. The one-grain mixtures of the pure alkaloids were very slightly fluorescent. The portions of these preparations tested could not, perhaps, properly be considered as of the strength given, as, even after they had been kept many days and agitated scores of times, the whole of the substances introduced would not dissolve; very little of the pure alkaloids seemed to be taken up by the water. The liquid examined was in each case bitter. The addition of a few drops of sulphuric acid markedly increased fluorescence, probably by bringing about complete solution or molecular distribution. The sulphuric acid and distilled water alone did not yield fluorescence.

The weaker acidulated solutions examined by me were found to exhibit the most decided fluorescence. Rhoads and Pepper, in testing for the relative degrees of fluorescence of the sulphate of quinia and the sulphate of cinchonina, compared, as I have already stated, a solution of ten grains of the former with one of twenty grains of the latter. They observed that the fluorescence of the solution of the salt of cinchonina, although twice as strong as the quinine solution, was much less intense than the latter, and hence inferred that the sulphate of quinia was by far the more fluorescent substance. Their conclusion is probably nearly correct, but their method of determination was wrong, and might lead others astray. Solutions of ten grains to the ounce have always appeared to me to be more positively fluorescent than those of twenty grains of the same body; and with still weaker preparations, unless the dilution is carried to an extreme degree, the property we are considering is much more marked. Stokes, in his first paper, in some remarks on the "Effects of Concentration and Dilution," treats of the fact that a solution which, when in a concentrated state, shows no sensible fluorescence, will

often exhibit, when much diluted, a copious appearance of that nature. He also advances a theory in explanation of this apparently paradoxical phenomenon. The degree of dilution which solutions can undergo without losing their fluorescent properties is something remarkable. I have already referred to the extraordinarily minute quantities of the sulphate of quinia which were found by Bence Jones to yield fluorescence; and I have ascertained that the same general fact is true of the other sulphates of the cinchona alkaloids. On several occasions I have examined solutions highly diluted,—at least to the $\frac{1}{100000}$ of a grain,—which have proved to be very positively fluorescent; but I have not as yet been able to make exact determinations with minute amounts, and I introduce these remarks chiefly by way of caution to other investigators.

With the acid solutions of the salts of cinchona I have performed numerous other experiments, mostly in imitation of the investigations of others with quiniferous preparations,—such experiments, for example, as analyzing the blue beam with Iceland spar and selenite for polarization phenomena, and the examination of solutions with colored glasses placed so as to intercept the incident or dispersed light, or both. I will defer the consideration of these matters to another time; and I hope also in the future to be able to give some observations on the fluorescence of the tissues before and after the administration of various substances. A method of observing fluorescence which I have sometimes employed, and which is called by Stokes the mode by *superficial projection*, is as follows: In a darkened room an alcohol flame is held close to a bottle or vessel containing the solution to be examined, which is poured into a wineglass or tumbler, holding the flame immediately over it, and placing the eye a little below the plane of the surface.

The study of fluorescence leads to a possible and, it seems to me, reasonable explanation of *cinchonism*,—the peculiar disturbance of the system caused by large doses or the protracted use of the alkaloids of cinchona.

That all matter is in motion is one of the best-established principles. Different physiological and pathological states prevail according as the conditions of motion in the body vary. Every sensation, and even consciousness, is a mode of motion. The universal ether upon which light travels not only pervades all space, but also permeates all matter. Young says that it passes through the solid mass of the earth as the wind through a grove of trees. It communicates its thrill to, and receives motion from, the atoms and molecules with which it intermingles. Fluorescent substances lower its rates of vibration, and those of the atoms or molecules. To this change are to be attributed the phenomena of cinchonism, and ultimately all the effects produced by the alkaloids of cinchona.

An illustration of Dove's, from Schellen, may make my idea clearer. He describes an ideal instrument. In the middle of a large darkened room he supposes a rod set in vibration and connected with a contrivance for continually augmenting its speed. Entering the room just after it begins to

vibrate, eye or ear cannot recognize its presence. Only the hand can feel its strokes. Soon the vibrations increase to thirty-two per second, and a deep hum is heard. The tone rises continually in pitch to the shrillest note, until the limit of sonorous vibrations is passed, when all again is silence. Warmth begins to diffuse from the rod, whose rate of vibration is still augmenting. Sound-motion has been transformed into heat-motion; but still all is dark. The vibrations increase in rapidity, and a faint red light begins to glimmer. Heat-motion has passed over into light-motion. The light brightens to a vivid red, and then is changed successively to orange, yellow, green, indigo, blue, and violet, when all again is swallowed up in night. The enormous sum of seven hundred and eighty-nine millions of millions of vibrations per second has been reached and passed.

In this illustration, sound, heat, and light are beautifully brought before the mind as modes of motion; and it may help us to comprehend processes going on in the body.

Let us for a moment imagine an instrument the opposite of that of Dove's, in which a rod, starting with a maximum number of vibrations, has connected with it a contrivance for continually decreasing its speed. Beginning with a rate which corresponds with the ultra-violet or Ritteric rays of the spectrum, the motion of the rod goes on diminishing, and it emits light which corresponds successively to all the colors of the Newtonic spectrum, from violet downward. Luminous motion then passes into that of heat; next, into sound-motion; and, finally, into mere mechanical movement.

Fluorescent substances act upon the ever-swinging molecules of the body somewhat as the contrivance for producing uniformly-decreasing velocity operates upon the vibrating rod. They lessen the speed of molecular vibration, and bring about effects in accordance with the lowered rates of motion.

Ring or buzzing in the ears is one of the first symptoms of cinchonism or *quininism*, as the effect is sometimes called when the sulphate of quinia is the particular drug introduced into the system. In our ideal instruments we had, in the one case, sound-motion passing up into that of heat; and, in the other, heat-motion passing down into that of sound. By the use of the alkaloids of cinchona—these slowers of vibrations—molecular motion is reduced until it comes within the range of acoustic phenomena. The auditory nerve and a portion of the brain-tissue, perhaps, are made to thrill with those vibrations which give rise to the peculiar subjective impressions of sound that are experienced in the early stages of cinchonism. Disturbed vision, or loss of sight, is another symptom of cinchonism sometimes present. Waves of light must hit the retina a certain number of millions of millions of times in order that the act of seeing shall be perfectly performed, and the molecules of the retina must oscillate in response to the number of shocks or impulses which they receive. If the retina could be shaken seven hundred and eighty-nine millions

of millions of times per second, violet light would be produced in a place shut out from all external luminous sources. Molecular motion is so impeded by the preparations of cinchona, when given in excess, as to prevent the nerve-apparatus of the eye responding to the proper number of vibrations. Advanced symptoms of cinchonism, such as headache, delirium, stupor, deafness, blindness, prostration, convulsions, and paralysis, might, in like manner, be traced to a clogging of the molecular wheels of the body.

Such expressions as "periodic diseases" and "antiperiodic remedies" are suggestive, when coupled with the fact that fluorescence, which belongs so markedly to the preparations of cinchona, is the result of the reduction of *periods* of molecular vibration. An immense number of substances are to a greater or less extent fluorescent, and in the lists of highly sensitive bodies are not a few of the most prominent articles of the *materia medica*. Calorescence, the effect produced when vibrations are increased in rapidity, is also the attribute of many substances. The degrees of fluorescence of the alkaloids and salts of cinchona, and of other fluorescent medicinal substances, may be the measure of their therapeutic efficacy in many diseases; while calorescence may provide a means of determining the value of a class of bodies which act in an opposite manner upon the animal economy. These two properties or phenomena at least afford fertile hints to the thoughtful physician, who looks and longs for some scientific method of ascertaining the curative virtues of the remedies which he is compelled to employ.

The experiments of Jones and Dupré, and of Rhoads and Pepper, have proved that animal fluorescence is increased after the administration of the sulphates of quinia and of cinchonina. It has also been shown that fluorescence is decreased below a normal standard in malarial affections, and that it rises in the scale *pari passu* with the giving of the cinchona preparations, and the improvement in the symptoms of the diseases. My own experiments, some of which I have detailed in the present article, have demonstrated that the sulphates of quinia and of cinchonina are also decidedly fluorescent substances; and I have also determined, approximately at least, the relative degrees of fluorescence of the four salts of the alkaloids of cinchona, which order may correspond with that of the antiperiodic power of these drugs.

The whole subject of fluorescence is one of broad and beautiful suggestiveness to the medical profession, apart from the practical fruit which it has already yielded, and which it promises to future investigators. Its phenomena are among the links or bridges by which the truths of organic and inorganic nature are to be more closely united, by which physics, physiology, and pathology are to be brought more nearly to the same plane of thought. "Molecules," in the language of Clerk Maxwell, "are the foundation-stones of the material universe." Even the microscope, biology's strongest weapon, must at times give way to that eye of our inner being which visualizes the invisible; unless, indeed,

the anticipation of Newton be realized, and the world blessed with an instrument by means of which the very molecules of matter can be observed while performing their now too often mysterious vocations. Let us occasionally endeavor to look within the sacred circle drawn around these swinging molecules, even though the effort should cause our ideas to be separated, as far as the ocean sunders different climes, from that humoral pathology which too long has dominated medical thought. Instead of going in pursuit of mythical blood-poisons and impossible disease-germs, whose presence and action in the system cannot be satisfactorily demonstrated, let us, in the play of the molecular forces, seek for the solution of those mysteries of therapeutics and pathology which have for years and ages baffled the powers of the acutest minds. The ultimate problems of disease, as of all nature, are questions of molecular physics.

ON CERTAIN PECULIAR SWELLINGS OF THE CRANIAL BONES CAUSED BY RICKETS.

BY R. W. TAYLOR, M.D.,

Surgeon to the New York Dispensary, Department of Venereal and Skin Diseases; one of the Physicians to Charity Hospital, New York.

I WISH to call attention to a rachitic condition of the frontal and parietal bones, which is interesting as being one of the scarcely recognized affections produced by that disease, as well as of importance in its diagnostic bearing. It seems to be a somewhat rare condition, seeing that many observant authors on rachitis fail to mention it. In the first place, in order to understand the condition, it is well briefly to call attention to the changes which rachitis produces in flat bones as well as upon the shafts of long bones. In the growing condition of these structures in the rachitic subject, the proliferation of connective tissue under the periosteum is often abnormally profuse, and the capillaries undergo corresponding increase. At the same time the ossifying processes do not take place: consequently we find upon incision in such a case, instead of true bone, a soft tissue, resembling the pulp of the spleen. It is this condition of softness and immaturity of the bone which predisposes to craniotabes, when the lesion is developed upon the occiput, though in very many cases the stage of periosteal swelling escapes observation. Under the influence of the pressure of the growing brain and of the weight of the head upon the pillow, more or less absorption takes place, and we find the typical soft occiput. This condition is well known. A similar periosteal proliferation very often takes place at the sutural margins, which are then much thickened. Thus far the lesions of the cranial bones due to rickets are quite well known. But in some exceptional cases this same lesion of the periosteum occurs on the frontal and parietal bones, and then, owing to their situation, and to the fact that they are not submitted to external pressure, an elevation occurs which may remain permanent or may disappear. These elevations are important, as they may be mistaken for syphilitic nodes, and a mistake of diagnosis, with

the consequent error in treatment, would be very serious in a case of rickets.

As usually found, these swellings, which may occur on either the frontal or the parietal bones, but more frequently upon the former, are flat, broad, and circumscribed. When this same periosteal lesion of rickets is developed on the shafts of the long bones, the tumefaction is more or less general, not strictly limited as it is upon the cranial bones. This feature of the circumscribed condition of these swellings is mentioned by Rindfleisch, who casually adverts to them. In their course these swellings grow rather slowly; rise to a height of about one line or a line and a half above the plane of the bones, even less than this, and present a smooth, rounded margin. Their surface is usually quite flat, and no nodulations are to be felt. Upon pressure, the tissue composing them feels quite firm; indeed, they are very liable to be taken as thickenings of the bones. In area, they occupy spaces of from half an inch to three inches in diameter, and they may be round or oval; generally their contour is markedly rounded. They may occur only upon one side of the skull, or, again, they may have a symmetrical distribution. Like all of the osseous lesions of rickets, they run a subacute course, and do not cause any inflammation of the skin, nor are they the seat of pain. Though not very salient, they induce visible deformities, which when occurring on the frontal bones are strikingly prominent. As to the period of apparition of these lesions, it may be stated that they are developed coincidentally with or subsequent to other rachitic osseous affections. The swellings on each side may appear simultaneously, or they may be developed at different times, even with as long an interval as several months. The following case will show the cause of these swellings:

Patrick Mc— was at birth a strong child, born of healthy parents. Without known cause, he became ill when six months old, his symptoms being those of rickets. At this time swellings of the ribs, radii, and ulnæ were developed. At his ninth month a swelling upon the left frontal bone was found; and when it was a year old a similar swelling developed on the right side. When this last swelling had existed four months, I saw the child, and found that the older one was rather more than an inch and a half long by three-quarters of an inch wide, and the smaller one was half of that size. The same characters were observed as have already been given. Under proper treatment and change of air the child improved, and the various swellings diminished in size. As the shafts of the bones of the fore-arms had been affected, a slightly curved condition was induced. The swellings on the frontal bone subsided in a rather peculiar manner: a slight depression was observed in the centre of each elevation, and gradually increased until scarcely any prominence of bone was discoverable. At one segment of the margin of the right swelling, a slightly curved elevation of bone about one-sixth of an inch broad and an inch in length was found.

This case shows very well the course of these swellings when resolution takes place in them. The next case will, in a like manner, show how perma-

nent distortion of the bone may be induced. There is also in it a coincidence of lesions which is interesting as to the diagnosis.

M. E., a female, aged 14, an inmate of a charitable institution, came under my care in February, 1869. She at that time had lupus vulgaris, which affected the whole of one cheek, running up to the forehead and scalp, and under the jaw. Her whole osseous system was much distorted by a rachitic condition, which had been developed when she was a child. Upon the right side of the frontal bone, near the median line, and about one-half inch above the supra-orbital ridge, was a swelling of that tissue. It was about half an inch high, and its area was about an inch and a half. Its shape was somewhat conical, and, its surface being smooth, its margins sloped imperceptibly into the surrounding bone. To the touch it was found to be firm, being evidently composed of true bone. There was not, nor had there been, any lesion of the integument. The peculiar coincidence of the swelling and the ulceration of the face were interesting. It occurred to me at first that perhaps the case was one of hereditary syphilis, but I did not feel satisfied, as there was no syphilitic character about the lupoid ulceration. Upon inquiry, I learned that the enlargement of the skull-bone had occurred at the same time that the other swellings appeared. As the girl gave a clear history of rickets, and as its sequelæ were present, I felt positive that the swelling on the skull-bone was of the same nature. I was also told by her that at one time it was not so prominent as it was when first seen by me. The case then was one of the peculiar periosteal thickenings of the frontal bones which are caused by rickets. In this instance, the pressure of the fast-growing brain within upon the soft and yielding though thickened bone produced a prominence, which in all probability was rendered greater by the natural tendency of the bones as they grew to be rounded just at this part. That is, that as the rounded natural condition grew more pronounced, owing to the weakened condition of the bone just here it became abnormally so, leaving this bulging swelling. When the girl was about nine years old, during the interval having been weak and debilitated, she was attacked by the lupoid ulceration of the face, which in five years had assumed the proportions I have mentioned. She had been but indifferently treated in the mean time. Various opinions were expressed upon the case by those who saw it casually and who did not inquire minutely into its history. Thus, imbued with the doctrines of the French school of dermatologists, one or two regarded the lupus as an evidence of scrofula, and argued that the bone-lesion was of similar origin; others, again, that the swelling was a syphilitic node, hence the case was one of hereditary syphilis, and the lupus was another expression of it. The real nature of the case is shown by its chronology, as well as by the knowledge of the history of these peculiar cranial swellings. In the order of succession, the girl's medical history is as follows: first, an attack of rickets of great extent and severity; second, a prolonged period of anæmia and malnutrition; third, the development of

an extensive lupoid ulceration. This conclusively shows that the supposed association of the osseous with the cutaneous lesion did not exist; hence, that the former was the expression of the rachitis, whereas the lupus was in all probability produced by the general malnutrition of the patient.

This case, then, shows very clearly that these rachitic periosteal swellings may remain permanent, and may produce deformities of the skull-bones. It is very probable, reasoning from the course of swellings of like origin upon the long bones, that they may permanently remain in their original shape. Again, they may undergo resolution by gradual subsidence, leaving, perhaps, no trace, or only a slight wavy elevation. Lastly, they may, under the influence of pressure, give rise to the prominent form of swelling as described in the last case, from the causes given. I am inclined to think that the swelling in the second case was not due to hyperplastic processes,—that is, that the bone was not any thicker in it than elsewhere, but that it was simply of the same thickness, or perhaps not as thick as the rest of the bone, being merely a bulging out in consequence of pressure. This is in accordance with what we know by observation takes place in other rachitic bones.

In a diagnostic point of view these swellings are very important, though they in their early stages differ markedly from the syphilitic node, which is more prominent and not so extensive, and which, moreover, is generally multiple. If their existence were not known, perhaps they might be looked upon as an unusual form of syphilis. If attention, however, is once called to their peculiarities, I think that no mistake will occur. In the prominent condition found in the second case, there is more likelihood of error; hence in such a case the history should be carefully elicited and considered, and then correct conclusions will be arrived at.

A CASE OF PARACENTESIS THORACIS.

BY E. T. BRUEN, M.D.

THE following case occurred in the Philadelphia Hospital during the past fall, while I was resident in the house. It affords such a good illustration of the advantages of paracentesis thoracis as a method of treatment in a class of cases frequently met with, that I offer it to your readers:

M. N., æt. 25, native of Ireland, was admitted to the white nursery with a strong, healthy baby three months old. She stated that she had been taken sick three weeks before, having been confined to bed seven or eight days. The physician who attended her told her she had pleurisy.

She suffered after she left her bed from constant dry cough, with but little expectoration. There was considerable dyspnœa, even when quietly sitting in a chair, and upon the least attempt to move about this became really painful. For these symptoms she applied for admission to the hospital, in order to subject herself to treatment.

Physical examination of the chest demonstrated complete flatness upon percussion from the second rib anteriorly to the base of the thorax on the left side, and

posteriorly the same signs from the angle of the scapula downward. Above, the percussion-note was greatly exaggerated, almost tympanitic. There was entire absence of any respiratory sounds over the area of dulness. Over the apex of the left lung the respiratory murmur was much exaggerated. The left side of the chest measured an inch and a quarter more in circumference than the right side, while there was scarcely any respiratory movement.

The heart was very slightly displaced towards the right side. The woman's general health seemed very good; no emaciation had occurred.

A large pleural effusion in the left chest was diagnosed, due to the recent attack of pleurisy, and, as medical agents proper for the case might perhaps have interfered with the secretion of milk, it was determined to resort to paracentesis thoracis.

I accordingly tapped the chest in the line of the axillæ in the sixth interspace, using an aspirator with a rather small-sized trocar, having first destroyed sensibility in the part by the local application of ice, and succeeded in removing forty ounces of clear serous fluid, which very soon became like a jelly in the pail which contained it.

After the operation, the wound was closed by adhesive strips, a dose of morphia given to allay cough, and a poultice applied to the chest.

No unpleasant consequences whatever resulted from the treatment; she walked about the ward the following day, and her cough and dyspnœa had completely disappeared. She was not allowed to go out for ten days afterwards, as the weather was unpleasant, but at the end of that time no restrictions were placed upon her habits, as she was quite well. Perfect restoration of the respiratory functions of the lung had taken place; only a slightly impaired resonance, due, probably, to a thickened condition of the pleura, remained to indicate that any functional disturbance had occurred.

The only medicine she took was a tablespoonful of Basham's mixture three times daily for two weeks. The poulticing was kept up at night for a week. During the day she wore flannel, which she was told to wear constantly hereafter.

December 1.—She is still an inmate of the white nursery, perfectly strong and well.

NOTES OF HOSPITAL PRACTICE.

JEFFERSON MEDICAL COLLEGE.

CLINIC OF PROF. S. D. GROSS.

Reported by D. C. ALLEN.

SARCOMA INVOLVING THE SCAPULA—EXCISION.

GENTLEMEN,—This man, R. L., æt. 21, presents the following history: Fourteen months ago his attention was attracted by a dull, throbbing pain at the inferior border of the right scapula. He had not received an injury in this location, nor was there any observable change in the appearance of the parts. Two months later, a small tumor was observed. Its growth was progressively slow; in eight months it had attained the size of a hen's egg; and pain was felt only when recumbent upon the affected side. After this, the tumor commenced to increase rapidly; the pain, though not severe, was constant, and this continued until two months ago, when the tumor ceased to grow and the pain almost entirely disappeared. On inspection, you here observe the tumor situated upon the scapula. It is about the size of a small fetal head; there is no discoloration of its surface nor enlargement of the superficial veins. On palpation, I observe that its tem-

perature is elevated above that of the surrounding parts; also that its consistency is uniformly soft, and its surface lobulated. Moving the mass to and fro, the scapula is carried with it, so that the tumor is evidently firmly attached to the bone.

From the history of its development, its form and consistency, I conclude that it is a tumor or morbid growth. But to what class of these affections does it belong? During its period of growth it bore a close resemblance to softer varieties of fatty and mucous tumors. But its occurring at this age, the history of its development, its consistency, its being lobulated, and its general appearance, lead me to pronounce it a sarcoma. I conclude that it is not carcinomatous from the fact that there is no enlargement of the superficial veins or involvement of the lymphatic glands,—those conditions being more or less constant concomitants of such tumors; while the absence of lymphatic involvement or enlargement of the superficial veins, and the lobulated form, are equally characteristic of sarcoma. The determining, however, to which of the malignant types such growths may belong is more interesting scientifically than from a clinical point of view, governed as all these types are by the same laws in respect to their origin, progress, tendency, and termination, and therefore requiring analogous methods of treatment. Of the causes of sarcoma, little is known: it is doubtful if it is ever hereditary; it is frequently spontaneous in its origin, but in many instances is traceable to local injury or irritation. It occurs with about equal frequency in both sexes, and may appear at any period of life, but is by far the most common between the twentieth and fortieth years, being rare before the former and very uncommon after the latter period. In reference to the treatment of this class of affections, it is rather humiliating to medical science that with all its potency it cannot make use of any measure that insures a permanent cure and immunity from recurrence of the malady.

All known local and internal remedies are alike useless either in arresting the progress or in preventing the occurrence of the disease. Nevertheless, much benefit may be effected by judiciously-directed general and local means,—by particular attention to the patient's diet, bowels, and secretions, and by the use of proper applications and attention to the affected part. Extirpation, while it cannot be relied upon as a means of permanent cure, and in many cases is positively contra-indicated, yet, under proper conditions, affords the most beneficial results of any measures which have been adopted; not only relieving pain and great anxiety, but also often resulting in more lasting benefit. This patient being in good health and of strong constitution, we are warranted in the employment of surgical measures. As the tumor involves the scapula to some extent, a sufficient amount of the bone will have to be excised to effect removal of the morbid growth. Excision of portions, or even of the entire scapula, as shown by statistics, is a warrantable operation, followed in the majority of cases by good results. On one occasion I removed nearly the whole of the right scapula for an osteo-sarcomatous affection from a man forty years of age, who made a good recovery, although, from the great size of the growth, an extensive wound was inflicted. Owing to the size of this tumor, the incision must necessarily be extensive, necessitating the division of a number of vessels, and more or less hemorrhage. The patient lies ready, and I effect the operation as follows. An incision, commencing on a level with the spine of the scapula near its middle, is carried downwards and slightly inwards, as low as the inferior angle of the scapula. The integument is dissected off from the morbid growth to the edges of the scapula on each side; and the muscles connected with the margins of the bone are detached. Passing my fingers under the scapula,

and raising it up, I sever its connection with the ribs, and, applying the bone-forceps half an inch below the spine of the scapula, cutting from without inwards, the last bond of attachment is divided, and the mass removed. The parts are excessively vascular, and bleed freely. Ten ligatures have been applied to arrest the hemorrhage, the patient having lost in all about twelve ounces of blood.

The wound will be allowed to remain open for two hours, when it will be approximated by sutures and adhesive strips, and the case treated on general principles. The tumor has the appearance of malignancy, but a microscopic examination will be made, and the results reported.

It is three weeks and three days since the operation, and you observe the wound is completely healed, and the patient is discharged to-day. The wound healed in great part by first intention. No dressing but lint and olive-oil was used; he took no medicine, was kept on light simple diet, and allowed to exercise in the open air.

Dr. West has examined the tumor. The larger part of the growth is connected with the dorsum of the scapula below the spine, measuring five inches in length, four in breadth, and two in thickness. It is lobulated, and apparently composed of numerous small growths. On dissection, the *infra-spinatus* muscle was found to be expanded into a thin sheet covering the posterior surface of the mass. The deeper layer of fibres are denser and more brittle than the superficial. This condition is also noticed, but to a greater extent, in the *triceps* and *teres* muscles. Microscopical examination reveals the presence of round-celled sarcoma tissue between the primitive fasciculi of these muscles, separating and compressing them. On the ventral surface of the bone a smaller growth is seen, which until the removal of the *subscapularis* muscle was not noticed. It is intimately adherent to the fibres of that muscle, the *sarcolemma* being invaded with the cells of the growth. The two growths are continuous through a perforation in the scapula. Section of the larger growth reveals at the lower extremity a soft, white, jelly-like substance, which exudes like the contents of a cyst. Higher, the tissue is of a darker color, and firmer, the color and consistence varying, however, in different portions of the growth. In some places the tissue is firm, arranged in bands which divide the mass into cavities, in which the softer portions are lodged. The color varies from purplish, through red and yellow, to white.

TRANSLATIONS.

LOCAL ACTION OF ICE ON THE ANIMAL ORGANISM (Dr. Frédéric Schulze).—The diminution of caloric in the system in general has been studied in a thousand ways, but nothing is known physiologically in regard to the local application of cold; the modifications which it produces at its point of application and in the entire organism have been ignored. This seems all the more incomprehensible, since the application of ice has come into such general use. This *lacuna* M. Schulze has endeavored to fill. The first question to be solved was the following: Does, or does not, the local abstraction of heat produce diminution of temperature in the more deeply situated organs? If it does, does this effect diminish with the greater depth of the organ, or does it present some other character? This question has been, up to the present time, solved in various ways. But observe the results of M. Schulze's experiments. Lowering of temperature by the local application of ice diminishes with the depth. The intestinal gases are

worse conductors of heat than the fluids of the encephalon, and hence ice applied to the head produces a more decided effect than when applied to the abdomen. After prolonged application of cold to the abdomen, the temperature falls one degree. For the lungs, which are saturated with liquids, the reduction is more considerable. No initial rise of temperature was observed, even in unnarcotized dogs.—*Gaz. Heb.*; from *Deutsches Archiv f. Klin. Med.*, 1874. X.

DIABETES MELLITUS, INTERCURRENT VARIOLA, AND DISAPPEARANCE OF GLUCOSE FROM THE URINE (Dr. M. de Carvalho: *Gazette Médicale de Bahia*, Jan. 1875).—A man æt. 25 years, small in stature, well developed, though emaciated and feeble, was admitted to the Infirmary of St. Vincent, in Bahia, November 12, 1874. He was a laborer by occupation, and a native of the province. He had been a sufferer from diabetes mel-

litus for two years, previous to which he had had good health, and no cause could be determined for the disease. The early symptoms had been great weakness in the inferior extremities, increased appetite, great thirst, and copious urination. Digestion was good, and there had been no disturbance of vision, or dermic eruption. Skin was hot and dry. No trace of disease could be found in any organ. The urine was the color of orange-juice, but lacked its characteristic smell, and the quantity voided in twenty-four hours was 4300 grammes, specific gravity 1035. Trommer's test showed presence of much sugar. A diet of animal food was ordered, all farinaceous food was forbidden, and a few laxatives were administered. Unfortunately, variola supervened on the twelfth day after admission, and the results of treatment were negative.

The following table shows the disturbance created by the acute disorder :

DATE.	COLOR.	ASPECT.	QUANTITY IN TWENTY-FOUR HOURS.	TEMP. C.	SP. GR.	REMARKS.
Nov. 13	Pale.	Limpid, with a little mucus.	4300 grammes.	25.5°	1037	
" 14	"	" " "	4200 "	26°	1034	
" 15	"	" " "	1895 "	26 4°	1034	
" 16	"	" " "	2100 "	24.5°	1036	Less thirst; copious perspiration.
" 17	"	Turbid.	1750 "	23.1°	1034	
" 18	"	"	1750 "	27°	1034	Transparent when fresh; less sweat.
" 19	"	"	1435 "	27°	1034	Red precipitate by Trommer's test.
" 20	"	"	1575 "	25°	1036	
" 21	Yellow.	"	1050 "	26.2°	1036	
" 22	"	Limpid.	1575 "	25°	1036	
" 23	"	Turbid.	1400 "	25°	1033	
" 24	"	Limpid.	1050 "	24.6°	1025	Invasion of variola.
" 25	Orange.	Turbid.	1050 "	24.9°	1022	Red precipitate by Trommer's test.
" 26	"	"	700 "	25.6°	1026	Abundant sediment.
" 27	"	"	875 "	25.5°	1015	Negative reaction of sugar; no sediment.
" 28	"	"	425 "	26 1°	1014	Died at 5 o'clock P.M.

The quantity of urine and the specific gravity diminished in a remarkable manner after the commencement of the fever. Coinciding with these changes there was found a negative reaction for sugar.

The patient had not been vaccinated, and other cases of variola were in the hospital at the same time. There was no doubt of the diagnosis of diabetes and of variola. Several daily examinations gave the reaction for sugar.

The dorso-lumbar pain was very significant. The temperature rose to 40° C. the first two days, and then gradually descended to 38.5° C. The eruption began to show itself on the 26th, and was well marked on the 28th, but irregular in its development and distribution. Some pustules were small and discrete, others were full and confluent. The color was from a dark red to a livid hue, which foretold danger. On this day (28th) an intestinal hemorrhage came on suddenly, and further depressed the patient, so that he died.

The coincidence of these two diseases is unique, and worthy of record. The violent febrile reaction of one disease suspended the production of sugar, which before was in great quantity. Other diseases do this, but the sugar generally returns after the secondary disease passes away.

From several cases upon record, one may conclude that any severe febrile attack occurring upon diabetes may cause the sugar to disappear temporarily from the urine. It has happened in pleuro-pneumonia, panophthalmitis following an operation for double cataract, and in some others. This suppression and disappearance of sugar from the urine is a grave symptom, and generally foretells a fatal termination.

In one case of diabetes insipidus the quantity of urine evacuated in twenty-four hours was reduced to normal, and continued so, during an attack of varioloid, but increased greatly afterwards. A distinguished colleague

of Dr. De Carvalho, in Bahia, suffered from beriberi paralytica. He had a severe variola, and in three weeks arose from his bed, cured of both maladies.

W. H. W.

THERAPEUTIC NOTES.

SNOW AS A HÆMOSTATIC.—Dr. Hane (*Centralblatt für Chirurgie*, No. 38, 1874) recommends very highly snow as a means of preventing hemorrhage in those operations in which Esmarch's method cannot be used. A handful of dry snow pressed upon the bleeding wound he found in a case of tracheotomy to act most favorably, soaking up the blood like a sponge and arresting the bleeding.

IODINE caustic is prepared by dissolving four grammes of iodine in eight grammes of glycerin. It is used in lupus by applying it once every other day, and covering the parts with gutta-percha. This treatment is continued for several weeks.—*Canada Lancet*.

SCIATICA.—Dr. I. Pretz (*Wiener Medizinische Presse*) gives as his personal experience the following facts. Having an attack of sciatica for six months, he tried all the ordinary remedies, with no avail. Observing that his attacks were slighter after eating, he determined to eat as often as the pain recurred. This was often twelve times in twenty-four hours. He constantly improved under this treatment, and in about two months entirely recovered. Two other cases were afterwards treated with similar results. He accounts for the result by the development of heat from the food and drink.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JANUARY 23, 1875.

EDITORIAL.

WANTED—A LAW TO PUT AN END TO PROFESSIONAL MURDER IN PENNSYLVANIA.

WE are in receipt of the memorial of the committee appointed by the State Medical Society to approach our Legislature in regard to the subject of laws regulating the right to practise medicine. We shall not reprint the document, because it will be very widely circulated in the State, and because it contains little or nothing with which the profession is not already acquainted. Its arguments are forcibly stated, and are unanswerable. It is simply astounding that whilst hedges and guards are placed by law around the enclosure within whose sacred bar are the members of the legal fraternity, any one, no matter how ignorant he, she, or it may be, can practise medicine in this State at will.

Quackery, druggists prescribing, first-course students, ignorant half-educated "regulars," homœopaths, and all manner of medical villanies certainly hold high revel here undisturbed. It is notorious that very frequently young men, richer in ambition than in money or conscience, study at the colleges for five months, and then engage in practice in some rural district until they shall have saved sufficient money to pay their expenses during a tarrance in the city. Many of them practise in this way for years,—some permanently. Often, these worthies do not find a diploma at all necessary for practical success. But if one be wanted, it can be

bought very cheaply, or any professional chirographer will write one for a trifle, putting in a few extra flourishes to prevent the ignorant from perceiving that the college represented as being in St. Louis, Boston, or where not, is a myth, as, of course, are also the professors who sign the document.

About two months since, by a curious combination of circumstances, without violating the Code of Ethics, we saw in consultation a case which had been treated by a gentleman who, under the ægis of an "Eclectic" diploma, walketh as the pestilence at noonday among the lower middle classes of the northern portion of our city. The patient apparently was suffering from enteritis, producing more or less paralysis and consequent partial obstruction of the bowels.

With a peculiar reverential but self-important air, our doctor said to us in the ante-room, "Professor, I am no homœopath; I am a regular physician. I am no dealer in infinitesimals. I treat actively. This man wanted his bowels open. I was bound they should be opened, and, by our father Æsculapius, they have been. I gave this man, in thirty-six hours, one hundred and twenty grains of blue pill, half an ounce of turpentine, eight ounces of castor oil, and twenty-eight drops of croton oil;* then I put a blister all over his abdomen, and this morning he is being cupped." (With a flourish worthy of the Pharisee in the temple) "His bowels are open; he is better."

On going into the room, we found the poor wretch almost dying, with a pulse one hundred and fifty and thready, his abdomen a raw surface from a recent severe blister, but covered with rows of cups placed as closely and as regularly as could be, some filled to the top, others freshly put on for the second time, with the blood spirting into them. Turning to the patient and pointing to the cups over the raw surface, we said, "Don't these hurt you frightfully?" In the faint, hollow whisper of impending death came back the answer, "Of course they do, doctor; but," looking at his wife, about to become again a mother, with her three little children clinging to her skirts, "my family are dependent on me; I would suffer anything to get well." Of course the grave soon closed over this victim of legalized murder.

In Pennsylvania, such is the law that this harpy is before it guiltless.

No doubt this was an extreme case, but not such

* Dr. Taylor, in his work on Medical Jurisprudence, says that fifteen to twenty drops of croton oil might kill a healthy man; and a patient suffering from inflammation of the bowels would of necessity be more susceptible than a person in health.

a very rare one, we fancy. What with the regular colleges turning out yearly their hundreds of barely half-educated physicians, the irregular schools graduating any who can afford a fee, the independent candidates for professional fees who scorn a diploma, to say nothing of herb doctors, Indian doctors, old-women doctors, and their ilk, we in all honesty believe that the lower stratum of medical practitioners in this State actually kill or ignorantly allow to die hundreds and thousands of the poorer and even of the richer classes.

We are most strongly in favor of some legislation which shall check this unbridled license, for which, it may be thought, not the medical but the legislative profession is chiefly to blame. The medical profession, however, shares the responsibility. It is in a measure owing to its supineness in the past that murder stalks in the guise of philanthropy through every byway of our commonwealth, and enters not rarely even the palaces of the rich. Let the committee bring this memorial and its subject before our legislators in such a way that they must pause from party wrangling to grant a serious hearing; and then, if no good results, our skirts will be clear.

We are aware that it is hardly probable that any laws will be passed which will accord entirely with our desires; but better by far the lesser of two evils; better an examining board which leaves entirely out of view all questions as to therapeutics and examines only on the other branches, than no examining board at all; better even that the diplomas of the homœopathic schools should be recognized by the State, than that no diploma at all should be required.

By all means, if possible, however, let us do away with trusting to any diplomas, and have simply an examining board, without whose certificate of qualification it shall be illegal for any one to enter upon the practice of medicine in this State.

CORRESPONDENCE.

BALTIMORE, January 2, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—Medical circles have been comparatively quiet here during the holiday season just closed. Our three medical schools gave their classes a rest. At the Washington University, on Wednesday night, Prof. Chancellor, Emeritus Professor of Surgery, lectured on "Physics and Physicians," before a good audience of physicians and students. Dr. Chancellor filled the chair of surgery for five years, and contributed much to the success of the school. His lecture was rather dry, and lacked the freshness of a recent compo-

sition. One could not avoid the conviction that it had served as a valedictory or opening address at some former period.

The College of Physicians and Surgeons has, unfortunately, had some disagreement among the members of the faculty, over the question of filling the chair of anatomy. The majority elected Dr. Bevan to the position, whereupon Drs. Byrd and Murray resigned. The vacancies thus occasioned have been filled by the election of Dr. Erich to the chair of diseases of women and children, and of Dr. A. Atkinson to that of materia medica. The chair of physiology still remains vacant.

The medical societies are somewhat agitated over the provisions of the new health law, which went into effect yesterday.

The mortuary statistics of Baltimore have been proverbially unreliable, being made up from the returns of the different cemeteries,—no certificates being required. The new law allows of no interments without a certificate from a physician or coroner, and also requires regular returns of all births, except those of illegitimate children, to be made by the attending physician within six days after delivery. The law may not be perfect, but it is a step in the right direction. That a change was needed is indicated by the fact that according to our health reports *colic* was one of our most fatal diseases.

At the last meeting of the Baltimore Medical Association Dr. P. C. Williams related a case of temporary aphasia occurring in a young man who during the war had been a hospital steward, and, owing to exposure, had suffered from paralysis of the seventh pair of nerves, from which he had recovered. Having had some difficulty with his lady-love, it was noticed at breakfast next morning that his cup fell from his hand, and that he was unable to speak. He could understand all that was said, but could not command language to reply. In order to test the extent of his difficulty, the doctor asked him to write the name of the lady, which was Elise: he wrote, A-Ea-Elia-Ela, then gave it up in disgust. The doctor, thinking it was from temporary causes and temporary congestion, ordered potass. brom., gr. xxx; tr. gelsem., gtt. xl, t. d.

At the next visit he had so far improved that he wrote her name correctly on the second trial. To show that the cure was not complete, he was asked to write his own name, and Augusta was the result. The doctor's name he wrote Walli-Wallians. On the third morning he was entirely relieved, and could speak as well as any one. During the whole time he perfectly appreciated the fact that his answers were incorrect.

At the same meeting Prof. Arnold related a case showing some of the effects of syphilis on the nervous system. A man 38 years old, who had led a fast life, had imperfect paraplegia, which prevented locomotion. He could move in bed, but when he tried to get out he wriggled about and required assistance.

There was dimness of vision, some difficulty of speech, slow articulation, and partial paralysis of the left arm and hand. There were suspicious patches between the

shoulders, deficiency of hair and eyebrows, and scars in the groin. Dr. Arnold, thinking that antisyphilitic treatment would be of benefit, gave one-sixteenth of a grain of corrosive sublimate thrice daily, and in fourteen days there was much improvement in the general condition, as also in the local symptoms, with the exception of vision and speech. He remained in hospital only five weeks, so that a complete cure was not effected.

Prof. Chew asked whether the presence of muscular power in connection with inability to walk did not seem to indicate locomotor ataxia; whether the syphilitic poison may not have affected the nervous centres, and thus have produced a syphilitic form of locomotor ataxia.

Prof. Arnold did not think so. The pains like electric shocks, met with in ataxia, were wanting. The defect in vision was confined to one eye; the manner of walking was different: the man swung his leg around, and did not bring his foot down flat. The partial success of the treatment was also a point in forming a correct opinion.

Several gentlemen related cases showing the tolerance and beneficial effects of large doses of potass. iod. Dr. Murdock has given as high as grs. lxxx three times a day, with less disturbance to the system than gr. v to x usually produce. The most marked change was in the pulse, which always increased from 70 or 80 to 90 or 100 beats per minute. More anon.

MEDICUS.

HOSPITAL OF THE P. E. CHURCH, January 9, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—The *Medical Times* of January 9, 1875, received, and contents in reference to the Episcopal Hospital noted, and I respectfully state, first, that no application from the Dispensary Staff, as a staff, has been received by the Board of Managers for the appointment of specialists; secondly, that a portion of the physicians of the Dispensary Staff have applied to the managers to take the matter of appointing certain gentlemen as specialists into consideration, and they, the managers, hold the matter under advisement, waiting further information on the subject. Hence you will perceive that you were incorrectly informed in the first place; and, as no action has been taken by the Board in the matter, you are premature in your statement in the second place; and hence you have no case at all.

Truly, yours, S. R. KNIGHT, M.D.,
Superintendent.

[We are glad to learn that, having been misinformed as to the facts, we "have no case at all," and hope the Episcopal Hospital may soon openly join the band of progressive institutions.—ED. P. M. T.]

REMOVAL OF FOREIGN BODIES FROM THE EAR (*The Lancet*, December 5, 1874).—Dr. John Cleland suggests that in removing foreign bodies from the ear the point of the probe or needle used for extraction should be placed *below* the object to be dislodged. By so doing it is placed between two inclined planes, and is readily and easily expelled.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

CONVERSATIONAL meeting held Wednesday, October 28, 1874, at 8 o'clock P.M.

VICE-PRESIDENT DR. I. S. ESHLEMAN in the chair.

Dr. STETLER asked what the experience of the members was in regard to the prolonged use of chloral hydrate. He had seen statements of its bad or injurious effects upon the brain, spinal cord, heart, mucous membranes, etc., from long-continued use, and was very anxious to learn the truth or falsity of the statements. He has a patient, æt. 75 years, to whom he has given it at bedtime in from eight- to fifteen-grain doses for four years, to procure sleep. The patient, having read of the terrible effects of its prolonged use, was unwilling to continue it, but could get no sleep without it, having lain awake for five hours, and then felt himself compelled to resort to the accustomed dose. There is no pain, but great nervousness, and the patient seems disposed to attribute part of the latter to the long use of hydrate of chloral. Can this be so?

Dr. WILLIAM GOODELL thought that so potent an agent as chloral could not be continuously used without grave constitutional symptoms. Clinical observations to that effect had, in fact, been frequently reported in the medical journals. It is, notwithstanding, a most valuable medicine, but in the long run not so trustworthy as opium, for it frequently induces a maudlin intoxication instead of the desired narcotism. A few doses of fifteen grains each, administered every quarter of an hour, will not only allay the sufferings of labor, but also dilate a rigid os uteri without weakening the expulsive pains. In this respect its action is decidedly superior to that of opium. In puerperal convulsions forty grains by the mouth or two drachms by the rectum, repeated at proper intervals, had, in his hands, acted like a charm. He attributed the strong prejudice which some physicians entertain against this drug to their unfortunate experience with an impure article which was shoved on the market some three or four years ago. It caused an inexplicable epidemic of wild delirium and of transient but violent mania. Quite a large number of these cases occurred in the practice of his friend Dr. H. Y. Evans, who was led to investigate their cause, and, finally, to discover it. If his memory served him no trick, this impure article was imported in the form of round dingy slabs, as large as a dinner-plate.

Dr. YARROW asked Dr. Goodell whether he had found chloral equal to full doses of morphia as an agent for dilatation of the os; morphia, in his experience, did not always allay, but rather seemed to increase, the uterine efforts.

Dr. BURNS, of Frankford, said that he had used hydrate of chloral considerably for several years, and was favorably impressed with its effects in the case of a lady suffering with irregularity of the heart's action and much wakefulness. She used it for two years with much benefit, and is now comparatively well. In another case, that of a very intelligent gentleman, he had used it for the period of one year. This gentleman was affected with extreme noises in his head, dreading to fall asleep, for in doing so these noises, as he figuratively described them, seemed to him as if all nature was in chaos, "and the elements crashing together." This case seemed as if epilepsy was about setting in. Chloral in this case has done good service; more so than bromide of potassium, which was used freely. A very unpleasant feeling of oppression came on, with

faintness and inability to expire, the air passing out of his lungs, as he described it, "in a whistling manner." Dr. Burns, thinking this might in some way be due to the anæsthetic effects of the chloral, suspended the drug and substituted extract of nux vomica, with the result of relieving him very soon; neither has the dyspnœa returned. In a very severe case of tetanus in a boy, produced by the cicatrix of a wound on the face from the kick of a horse, it was the chief means of cure, although cannabis indica, bromide of potassium, hypodermic injections of morphia, etc., had been freely used. This case continued six weeks; injury to the supra-maxillary nerve being the pathological condition.

In mania a potu, the chloral has done good service in his hands. It produces less cerebral disturbance after its use than opium and its preparations. Neither does it, in his opinion, produce the habit or craving for its continuance, as opium invariably does.

In cases of insomnia, irritability of the nervous system, and general restlessness, he has been in the habit of giving ten grains before bedtime, repeated in half an hour; if not composed, continue hourly until the effect is produced.

He believes chloral to be contra-indicated in cardiac debility, phlegmatic temperaments, or in cases of exhaustion from shock, or low condition of vitality, where there is much vascular excitement with a free pulse and nervous tension.

Dr. H. H. SMITH said, in his experience it was an uncertain remedy. In one case of delirium tremens he had given one hundred and twenty grains at one dose, and afterwards another of seventy. In another case twenty grains were given every two hours without any perceptible effect. He said he had no doubt as to the reliability of the drug he had used.

Dr. ATKINSON agreed with Dr. Goodell. He had found chloral very useful, and especially in puerperal convulsions. He thought that the fact that there were some forms of the article that did not seem good, and were apparently without effect, might account for Dr. Smith's experience.

Dr. HAMILTON said, in reply to a question by the President, that his limited experience with chloral had led him to think that its action was somewhat irregular, falling short of, or exceeding, at times, what had been anticipated. In regard to its beneficial influence in certain obstetrical conditions, the evidence seemed to be favorable. In one of these conditions, however, —misplaced labor-pains,—in some instances exceedingly severe and vexatious, there was, perhaps, no medicine so useful as opium or morphia, dependent for their tranquillizing effects in such cases probably to their well-known power to re-establish perverted correlative movements of the nervous system.

Dr. COLLINS read an abstract, a translation from the *Wiener Medizinische Wochenschrift*, a case reported from the Gynäkologie University, Clinic of Prof. Karl Von Braun Fernwald, entitled "A Case of Extra-Uterine Pregnancy, with Rupture of the Ovum in Early Period of Pregnancy and Development of the Fœtus in Abdominal Cavity to Full Period."

Dr. D. HAYES AGNEW said he had not had a large experience in these cases. During the last five years he had seen three cases. The last case progressed as a normal pregnancy. She engaged her doctor. She was taken in labor, and her physician summoned. The progress being delayed, a consultation was called. No advancement being apparent, another physician was called in to take charge of the case. He was, at this juncture, called to see the case, and on examination could trace what was supposed to be an arm or leg through the abdominal parietes, the head lying in Douglass's cul-de-sac. The symptoms became urgent, and the child, full-grown, was removed through the pos-

terior wall of the vagina. The placenta was found loose, and readily extracted. The patient did well for a few days. An injection of a solution of the permanganate of potassium probably caused the inflammation of which she died. The attachment of the placenta was not determined. Another case was in the northern part of the city. She went beyond the normal period of gestation. The uterus was retroverted. There was retention of urine, and a prominence in the recto-vesical pouch along the side of the uterus. His first impression was that it was an abscess, but the use of an exploring-needle procured a fluid like the liquor amnii. The case died, and although no thorough post-mortem was permitted, yet it was sufficient to determine that the cause of death was hemorrhage. The third case died of peritonitis.

Dr. ATKINSON spoke of a case of extra-uterine pregnancy in the hands of an irregular practitioner. The child had died two months before its full term. The child was passed per rectum in pieces, such as parietal bones, hair, ribs, etc. The mother's suffering was intense, but she has recovered.

Dr. GOODELL remarked that he had seen two very distressing cases of death from tubal and one from a ventral pregnancy. He had first mistaken the latter for an attack of pelvic peritonitis, and afterwards for a retroversion of the gravid womb, before he had arrived at a correct diagnosis. He wished to deliver the woman by an incision into Douglass's pouch, but was overruled by her friends. He attributed the absence of a cyst in Dr. Collins's case to an early and bloodless rupture of the Fallopian tube. The fœtus escaped into the cavity of the abdomen, and had lived on, because its mother had survived this accident, and because the placenta had not been dislodged. He believed that extra-uterine fœtations without cysts would be more frequently met with were it not that, upon the rupture of the tubal cyst, the woman usually perishes from hemorrhage.

He was called to see a patient Aug. 1, 1873, nearly three months married; no menstrual show since marriage, though regular previously. Complaining of severe pains as though threatening abortion. General symptoms of pregnancy having been manifest, she was placed upon usual treatment, which was effectual so far as to relieve symptoms. Aug. 5, his attention was called to a darkening of umbilicus; slight pain had been continuous since last visit; there now appeared a show of blood from vagina. Aug. 8, pain renewed with great severity, continuous, but greatly exaggerated at intervals; patient very weak and in great nervous excitement. Aug. 9, symptoms much the same. Aug. 10, sudden fainting, cold perspiration, pulse very rapid, tendency to collapse; uterus normal in size; parts very sensitive, hot and throbbing. Supposing a case of tubal fœtation, consultation was asked. Two physicians saw the patient, one Aug. 11, morning, in my absence; attributed condition to disorder of liver, and left suggestions (symptoms at this time had become milder). The other, in consultation, 1 P.M. of same day, suggested pelvic peritonitis, and an expectant treatment was entered upon.

Patient failed to recover as was expected. A tumor presented above the pubes, gradually becoming ovoidal and extending towards the umbilicus; skin becoming tense, and parts painful on pressure; a dull throbbing pain continues, extending to back; uterus still normal, but an enlarged mass back of and above it. This continued until Aug. 29, when, being seized with a strong desire to defecate, a gush of clotted blood and water nearly filled the chamber. An odor as of "rotten flesh" compelled the family to throw it away at once, thus preventing an examination. The tumor subsided at once, as well as all inflammatory symptoms. Rectal

examination revealed large rent above and back of the uterus, but tenderness of parts and debility of patient prevented further examination. No indications for treatment were present; parts healed kindly, and patient recovered with no untoward occurrence.

Dr. ESHLEMAN presented a specimen of an umbilical cord from a still-born child, that had expired a few days prior to birth. The cord was unusually short, and about twice the usual thickness. It was very firm, and imparted a gristly sensation when cut. The placenta was healthy in appearance. The child was well developed, and at the eighth month. This is the fourth child lost within four years, each preceding one about a month earlier than the following one. The third one was lost at seven months, being born alive, but respiration could not be well established before it expired. These children had no marks of disease about them. The father had suffered from a primary sore six years ago, accompanied with glandular swellings, which had been scattered without suppurating. Dr. E. attributes the death of these children to inherited syphilis, and sees in each child its gradual diminution, and proposes aiding its elimination in the parent by iodide of potassium, with the expectation of reaching at the fifth or sixth birth a viable child.

GLEANINGS FROM OUR EXCHANGES.

A NEW CATARACT-KNIFE (*The Lancet*, Nov. 28, 1874).—C. Bader, Ophthalmic Surgeon to Guy's Hospital, gives the following description of a new knife, which has of late been used to obviate the inconvenience arising from the inward movement of the eyeball when commencing the corneal incision in the operation for cataract. It so thoroughly answers its purpose that it can be recommended in preference to other cataract-knives. If, standing behind the patient, we wish to operate upon the left eye with the right hand, and upon the right eye with the left hand, two different knives—one for the right and one for the left eye—are required, unless the operator prefers using the right hand only, when the bent knife, used with the right hand for the left eye, may be used for the right eye also, commencing, however, the incision at the outer margin of the cornea. By the employment of the bent cataract-knife, commencing the incision at the inner margin of the cornea, great control is obtained over the movements of the eyeball, whether the incision be made upwards or downwards. The natural inclination of the eyeball to roll inwards towards the nose when operating in the usual manner, instead of being a source of trouble, becomes a help by the use of the bent knife. The blade is somewhat wider than that of Von Graefe's knife, the point is in a line with the back, and the blade is bent away from the handle in such an angle as to admit of easy access to the inner (nasal) margin of the cornea.

FLEXIBLE CATHETER FOR IRRIGATING THE BLADDER (*The Medical Record*, Dec. 1, 1874).—Dr. Stuart Eldridge describes as follows an instrument for the irrigation of the bladder in certain cases in which the rigidity of the ordinary instrument renders its use inconvenient or impracticable.

Through the side of a soft rubber catheter (No. 10 to 12, English gauge) an opening is made by a broad needle, or the point of a lancet, at the distance of an inch and a half from the open end of the tube. Through this opening force the point of an ordinary gum catheter of such size as to lie very loosely in the bore of the rubber instrument. In passing the smaller catheter into the larger one, the surface should be well wetted, and the stylet retained until the point of the gum instru-

ment has passed into that of the rubber one, when the stylet should be removed and the instrument is ready for use. In a similar manner an irrigator may easily be extemporized from an ordinary metallic catheter, either male or female, by adjusting upon the open end of the instrument a short piece of rubber tubing, through the side of which a gum catheter is passed in the manner described above.

NITRIC ACID AS A NERVE-DESTROYER (*The Lancet*, November 28, 1874).—At a recent meeting of the Medical Society of London, Mr. Napier related a case lately under his care, in which, the teeth in both jaws being reduced by mercurial salivation and other causes to the condition of sharp jagged spikes, productive of much suffering and discomfort, and anæsthesia in any shape being objected to, he had employed an original form of treatment, giving rise to no pain. The process of filling having been satisfactorily accomplished by means of the ether-spray, locally applied, he cautiously and very gently touched the exposed portion of the nerve of each tooth successively with a pencil of hickory-wood dipped in nitric acid, by which simple method it was rendered insensate, and the mouth prepared for the reception of artificial substitutes. Mr. Napier was anxious that the principle involved should receive a fair share of attention, as he held the present system of nerve-demolition to be at variance with true science.

DISLOCATION FORWARDS OF THE STYLOID END OF THE ULNA (*Edinburgh Medical Journal*, October, 1874).

—Mr. T. E. Purdom records the case of a man whose hand was accidentally pushed in between the rollers of a planing-machine, his fore-arm being likewise drawn in, in a slanting direction. The rollers, placed one above the other, gave a little, so far saving the arm. The hand and wrist were much twisted. On examination, the limb had a curious appearance, there being a hollow on the ulnar side posteriorly, while in front, just above the wrist, a hard swelling was felt, and was diagnosed to be the styloid end of the ulna, displaced forwards. The elbow being fixed, extension being applied to the hand, and pressure to the projecting bone, reduction was easily accomplished, the bone giving an audible click as it returned to its place. The fore-arm and carpus were then placed in two well-padded splints.

VERTICAL LUXATION OF THE PATELLA (*The Medical Record*, Dec. 1, 1874).—Dr. S. P. Davis reports the case of a servant-girl who, while sitting upon the floor, suddenly reached forward to seize a child, and found immediately afterwards that she was unable to move her leg.

On turning the patient upon her back, the left patella was plainly seen in a condition of "vertical displacement,"—i.e., turned upon its inner edge, so that its upper surface looked towards the opposite knee. It was rigidly fixed, and the limb was entirely helpless.

The patient was etherized as she lay upon the floor. The whole limb was then elevated by an assistant, so as to relax the muscles in front of the thigh, and, by forcibly crowding down these muscles towards the knee with one hand, manipulating the patella at the same time with the other, reduction was effected with the utmost ease.

TETANUS FOLLOWING SYME'S AMPUTATION OF THE FOOT (*The Irish Hospital Gazette*, December 1, 1874).

—Dr. Barton operated on a woman, æt. 43, who was suffering from an epithelial disease of the foot. He performed Syme's amputation, chloroform being used effectively, and Esmarch's bandage applied from the toes to above the ankle. The arteries were all twisted. Extensive sloughing of the flap took place. On the ninth day the patient complained of difficulty of swal-

lowing; on the tenth, all the symptoms of tetanus were well developed; spasms occurred with great frequency and severity, and on the following day she died. The treatment consisted of the administration of chloral, morphia, and enemata of beef-tea and brandy.

MISCELLANY.

A HILL OF SULPHUR.—One of the most remarkable deposits of native sulphur as yet discovered is a great hill composed of the almost pure article found some two years ago at a distance of thirty miles south of the Union Pacific Railway, and nine hundred miles west of Omaha. This marvellous deposit is found to consist almost wholly of sulphur, containing only fifteen per cent. of impurities. The best deposits heretofore available are those found in Sicily. The principal supplies for the manufacture of sulphuric acid come from there; the deposits contain thirty-five per cent. of impurities and sixty-five per cent. of sulphur. Our Western sulphur hill, therefore, is much the more valuable, and promises to become, ere long, of great importance to the country. —*The Drug, Paint, and Oil Trade.*

By royal decree, female students in Sweden are to be admitted on the same terms as males to all the examinations in the universities, except those for the licenses in theology and law.

A COACHMAN of an undertaker in London recently contracted smallpox by assisting at the funeral of a gentleman who had been brought from Jersey with the disease.

SOMETHING less than 180,000 marks have been devoted by the Berlin Government to the erection of a Seaman's Hospital at Yokohama.

The London *Lancet* is said to net an annual income of nearly twenty-five thousand dollars.

NOTES AND QUERIES.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—Dr. H. C. Wood, in his clinical lecture "On the Use of Digitalis in Diseases of the Heart," published in your journal Nov. 14, 1874, induced me to try it according to his mode of administration in certain cases, —i.e., in larger and more frequent administrations. I did so, and with the most surprising results in the patient's favor.

Mr. I., aged 63, was suffering from dropsy, due to two abnormal conditions of his heart,—mitral insufficiency and dilatation. He was treated with digitalis, about fifteen drops three times a day, morphia at night, etc. The dropsy was partially removed several times by the free use of elaterium, but quickly returned. He was now too debilitated to undergo a copious purgation. Moving his legs, even, was impossible. At the time the lecture referred to was published, he presented the following symptoms: pulse 130 and very feeble, respiration rapid and labored; at times a fierce short struggle would ensue for more air; face cyanosed; recumbent position impossible. The dropsy, as stated, was general, and near its maximum; the skin of his legs presented a purplish discoloration, and was stretched to its utmost tension; cough persistent and very troublesome, due, no doubt, to the infiltration of water in the lung-tissue. The patient, in short, was drowning, and, unless speedily relieved, must die. Urine albuminous and scanty. Ordered one-half grain of digitalis with one grain of squill every two hours. In thirty-six hours the pulse was down to 70—a full, soft wave greeting my finger; urine passing in immense quantities. Patient felt much better, and was sorry he did not have a grist-mill to run, since he could furnish the water-power. Medicine reduced to six administrations

a day, then four, three, two, and one. In eight days the dropsy had entirely disappeared, leaving the man almost a "living skeleton." His attenuated frame and wrinkled face told of the intense physical suffering endured before digitalis, in *doses large and oft repeated*, beat back the tide and manned the pumps. He sleeps well, eats well, and, with tonics and a liberal diet, is rapidly regaining his strength. There is now a buoyancy in the old man's step, and a warmth in his hearty grasp, contrasting strongly with the utter helplessness of his former state and the snaky coldness of his dropsied hands.

A. K. MINICH.

January 6, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—The following transcript may be of interest to your readers, and I give it in the hope that I may elicit some information in regard to the really frightful plague which is so briefly chronicled. The item I discovered this evening in an old colonial newspaper which announces itself as follows:

"NEW-ENGLAND WEEKLY JOURNAL,

"Containing the most remarkable occurrences, foreign and domestick.

"Monday, April 8, 1728."

And at the bottom of the second and last little page I find—

"BOSTON.—Printed by S. Kneeland and T. Green, at the Printing house in Green Street, where advertisements are taken in."

Among other foreign intelligence of the week is the following for November 11 (probably 1727):

"LONDON, November 11. . . .—The fever which raged here and in the country is very much abated as to its Frequency and Fatality; but they write from Amsterdam that for five weeks their Burials have amounted to 600 (!!) per week, and they have now risen to *seven hundred*; and it is reckon'd they had 40,000 persons lying sick in that city."

Can the above account be corroborated by contemporaneous evidence? or is the paragraph simply a feat of colonial journalism, that will put our latter-day *canards* to the blush?

SURGEON.

FORT STOCKTON, TEXAS, December 19, 1874.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—The following advertisement is culled from one of our daily papers. It is against ethics for specialists to advertise openly. Why does not the medical press protest against specialists advertising on the sly?

THE GYNÆCOLOGICAL HOSPITAL and Infirmary for Diseases of Children, No. 1624 Poplar street. Open daily (Sundays excepted), from 10 to 12 o'clock A.M., for the gratuitous treatment of respectable women suffering from diseases peculiar to their sex; also for diseases of children.

Attending Physicians: Dr. JOHN J. REESE, Dr. JOSEPH A. McFERRAN, Dr. THEODORE H. SEYFERT.

SUBSCRIBER.

["Subscriber" must be one of our numerous recent patrons; else he would scarcely have asked the question which he has.—Ed. P. M. T.]

DR. W. H. WINSLOW has been appointed Assistant-Surgeon in the Eye and Ear Department of the Children's Hospital.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A CONVERSATIONAL meeting of the Society will be held at the Hall of the College of Physicians, Wednesday, January 27, 1875, at 8 o'clock P.M. Dr. Cheston Morris will read a paper on "The Use of Alcohol in the Treatment of Disease."

The medical profession in Philadelphia are cordially invited.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JANUARY 12, 1875, TO JANUARY 18, 1875, INCLUSIVE.

CRONKHITE, H. M., ASSISTANT-SURGEON.—Assigned to temporary duty at Fort Yuma, California, and, when relieved by Assistant-Surgeon Loring, assigned to duty as Post Surgeon at Camp Verde, A. T. S. O. 113, Department of Arizona, December 26, 1874.

MOSELEY, E. B., ASSISTANT-SURGEON.—Assigned to duty at Mobile Barracks, Mobile, Alabama. S. O. 4, Department of the South, January 14, 1875.

SATURDAY, JANUARY 30, 1875.

ORIGINAL LECTURES.

ON FEVER.

ABSTRACT OF TONER LECTURE.

Delivered January 20, 1875.

BY H. C. WOOD, JR., M.D.

THE definition which declares fever to be "an acute derangement of all the functions," although certainly true, yet fails to give to the mind any idea of the phenomena of fever. When these are analyzed, it will be found that the most important of them are capable of being grouped in three sets: acceleration of the heart's beat and disturbance of the circulation; nervous disturbance; elevation of bodily temperature. Of these groups, the first two are merely secondary to and dependent upon the third: *i.e.*, the essential part of fever is elevation of temperature,—an excessive production of bodily heat. The demonstration of this fact necessitates the proving of the following propositions, the truth of which once acknowledged, the final conclusion becomes inevitable.

First: External heat applied to the body of the normal animal so as to elevate the temperature produces derangement of the nerve-functions, of circulation, etc., etc., precisely similar to those seen in natural fever, the intensity of the disturbance being directly proportional to the rise in temperature.

Second: Heat applied locally to the brain or to the heart produces those disturbances of the functions of the organ which are familiar phenomena of fever, the intensity of the disturbance being directly proportionate to the amount of heat in the organ.

Third: The withdrawal of the excess of heat in fever is followed by a relief of the nervous and circulatory disturbances.

When a dog, cat, or rabbit is confined in a heated atmosphere, the temperature of the animal rises, and at the same time the pulse-rate becomes *pari passu* more rapid, the breathing more hurried, and stupor, coma, partial paralysis, convulsions, and, finally, death occur. Although man is able to bear extremes of temperature far beyond the point which would prove fatal to any given species of animal, he is as susceptible as the animal to an excess of internal or bodily heat. The terrible mortality of sun-stroke, or thermic fever, is a witness to this susceptibility.

These facts, which have been developed more in detail elsewhere, are certainly sufficient to prove that an exposure to external heat will produce all the phenomena of fever.

In a series of experiments upon the action of heat on the nerve-centres, the brains of cats and rabbits were heated by the application to the head of a pig's bladder through which was passed a stream of heated water. It was found that coma, with or

without convulsions, was produced, sometimes coming on gradually, in other instances developing very suddenly; but in either case death was finally brought about by paralysis of respiration, or apnoea. As in these experiments it was found that pouring cold water upon the head at once relieved the coma, the conclusion is logically irresistible that the coma was produced by the heat. The degrees of temperature at which, in the locally-heated brain, consciousness was lost and at which death occurred, were found to correspond closely with the degrees at which the same phenomena took place when a general augmentation of the bodily heat was artificially produced.

It having been determined that heat applied to the brain of an animal is capable of causing cerebral symptoms similar to those seen in fever, the next point is the action of the same force on the heart. When the heart of a frog is removed from the body and exposed to a rising temperature, the pulsations constantly become more and more rapid until a heat-limit is nearly reached, at which the action of the heart ceases.

It is, of course, impossible to experiment directly upon man, but we have very direct evidence that heat affects his organs as it does those of animals. Dr. Liebermeister analyzed the records of two hundred and eighty cases of acute disorder not directly affecting the brain or heart, but accompanied by a rise in temperature, and the following table shows with what great regularity the pulse rises also:

Temperature (Cent.)	37°	38°	39°	40°	41°	42°
Pulse, Mean,	71.6	88.1	97.2	105.3	109.6	121.7

In regard to animals, then, the second proposition has been actually demonstrated by rigid experimentation, and in regard to man it is a scientific impossibility that it be other than true.

The proof of the third proposition is contained in the following experiment, which was repeated several times with similar results. A rabbit was placed in a heated atmosphere, and allowed to remain there until consciousness was entirely lost. It was then taken out and plunged into a bucket of cold water. The temperature of the body fell very rapidly to the normal point, that of the water rising at the same time, and consciousness returning as soon as the body was cooled. In a few minutes the rabbit was able to walk, and the next day had entirely recovered. A few moments' more exposure to the high temperature would have killed the animal: undoubtedly the consciousness was suspended by the action of the heat upon the brain, and undoubtedly it was restored by a withdrawal of that heat. A perfectly parallel series of phenomena occurs in man. A case of so-called cerebral rheumatism was reported by Dr. Wood in this journal (May 30, 1874), in which the patient was absolutely comatose, with a pulse of 160 and 170, and an axillary temperature of 108½° Fahr., but on being placed in a full bath at 60° Fahr. exhibited distinct signs of returning consciousness in a minute and a half, and in three minutes attempted

to get out of the tub. The temperature fell several degrees in a few minutes, and gradually became normal, and the patient finally recovered.

This case in connection with the experiments upon the lower animals seems to establish with absolute certainty the truth of the third proposition.

It having been proven that excessive heat is present in fever, that it is capable of producing the disturbances of innervation and circulation, and that its withdrawal is followed by instantaneous relief of those disturbances, the conclusion is logical that excessive temperature is the cause of the other symptoms of fever; that it is the essential portion; that fever and excessive bodily temperature are synonymous.

Having arrived at a clear idea of what fever is, we are now prepared to investigate its mechanism; to determine, if possible, in what way the rise of bodily temperature is produced.

In fever, all portions of the body are usually in unison, the increased tissue-change which must be at the basis of the elevation of temperature apparently occurring everywhere throughout the system. It is plain that there are only two bonds of union between all portions of the body,—two organs or tissues which fuse, as it were, all parts of the system into one, and that any physiological or pathological process which is equally shared by all must have its origin either in the blood or in the nervous system. Is fever, then, a hæmic disorder, or is it a neurosis?

Let us pause a moment to understand clearly what we mean by fever being hæmic or neurotic. If the poison carried by the blood into all parts of the body acts upon the various tissues everywhere in such a way as to increase in them tissue-change, or if, upon entering the blood, it excites such changes in that fluid as to cause it to incite the tissues everywhere to fever, then that fever may be called with scientific strictness *hæmic*. Suppose, however, we have a fever-centre in the nervous system, and that irritation of a peripheric nerve is capable of causing fever by affecting such centre; then the fever is certainly a neurosis. Granting the existence of a "fever-centre" of this kind, the laws of life teach us that there must be poisons capable of acting upon it so as to produce a fever, which would certainly be *neurotic*, although due to a poison in the blood. With this understanding of the terms, proof is wanting at present that the fever of pyæmia, for example, is strictly hæmic; it may be due to an action of the poison upon the central nervous system. There are, however, numerous fevers in regard to whose origin there can be no doubt, as that due to the irritation of a local inflammation, and especially the so-called urethral fever, etc., where the fever is due to an irritation that effects no local nutritive change, and must, therefore, be produced through the nervous system. A phenomenon which is in itself sufficient to prove that fever is not always due to a diseased condition of the blood is the confinement of the fever in some cases to a part, especially seen in malarial disorder. The conclusions to be drawn from the clinical consideration of the subject are that in some cases fever is undoubtedly a neurosis, whilst in

other cases clinical medicine is unable to decide with certainty whether the elevation of temperature is neurotic or hæmic.

Having investigated the origin of fever from the clinical point so far as we are able, it is evident that we must supplement this study by an experimental investigation directed to discovering to what extent and in what way the nervous system does influence animal temperature.

In 1870, P. Heidenhain announced the following results obtained experimentally:

1. Irritation of a sensitive nerve causes a rise in the blood-pressure, but a fall in temperature.
2. This fall occurs in the posterior part of the body even after the circulation has been entirely cut off by forcible compression of the aorta.

In order to determine clearly the truth concerning the influence of irritation of a sensitive nerve upon temperature, Dr. Wood has performed a number of experiments upon dogs and rabbits, in which the crural and axillary nerves were exposed and subjected to galvanic irritation, while a thermometer was introduced into the peritoneal cavity.

In no case did the temperature fall whilst the current was being applied, but in nearly every case there was a perceptible rise, amounting from an eighth to a half of a degree, and probably due to the rise of blood-pressure and the violent muscular exertion caused by the pain. It certainly occurred at the period at which the blood-pressure was increased. In many experiments upon the action of irritation of a sensitive nerve upon the arterial pressure, Dr. Wood found that if any rise occurred it was immediate, and that in a very brief time after the cessation of the irritation the arterial pressure became normal. The fall of temperature, however, did not commence until after the period of disturbance of the circulation, and in most cases it was very persistent, and progressively increased for many minutes. It is therefore evidently absurd to attribute the fall of temperature to disturbance of the circulation, since at the time of the fall of temperature the circulation is not profoundly affected.

From these data the conclusion seems logically inevitable that the fall of temperature which results from the irritation of a sensitive nerve is independent of the circulation, and is due to a direct influence of the nervous system upon the heat-producing functions of the body.

If the cord of a rabbit or other small mammal be cut in the lower cervical region, the temperature at once falls; and if the air of the apartment be decidedly below the warmth of the body, this fall is permanent. If, however, the animal be thoroughly wrapped in raw cotton or in wool, and if the external temperature be not too low, the fall just spoken of is but temporary, and is succeeded by a rise of temperature which passes far beyond the normal point, so that the animal dies in a state of intense fever.

The question here presents itself, Is the first fall of temperature due to a lessened production, or to an abnormal throwing off of animal heat? The fact that after the secondary fever has been developed the temperature will again fall if the animal

be exposed to cool air, certainly shows that the body throws off heat more rapidly than normal, the dilatation of the vessels in the lungs and on the surface, and the slowly-moving blood-current, being well calculated to produce such an effect. It is probable also that there is, immediately following division of the cord, diminished heat-production as well as increased heat-evolution. But, be this as it may, facts which it would be premature to bring forward at this time prove that the fall is directly connected with vaso-motor paralysis and the derangement of the circulation.

T. Tscheschin states that in a single experiment, instead of cutting the cord, he divided the medulla oblongata at its junction with the pons, and that the rise of temperature was in this case immediate, and not preceded by a fall. This fact has been entirely confirmed experimentally by Dr. Wood, who also found that, after galvanization of a sensitive nerve in an animal in which this section of the medulla had been practised, the same rise of blood-pressure as in the normal animal took place, showing that the section had been made above the vaso-motor centres.

Dr. Wood also found that the rise of temperature followed section of the medulla at the pons in animals in which the arterial pressure had been reduced to the minimum point by free venesection, as well as in those in which the arterial pressure was very great.

That the rise of temperature was in no wise connected with the respiration was proven by the fact that it occurred in all conditions of that function. Section of the medulla at the pons therefore produces a fever, which must be due to the cutting off of a repressive force,—i.e., there must be in the nervous system above this point a centre which controls the chemical movements of the body. This is in accord with well-known pathological facts, since free hemorrhage into the pons is followed by an enormous rise of temperature if the patient live a few hours. The fact that after hemorrhage in the neighborhood of the optic thalamus the temperature of the paralyzed limb is usually several degrees above that of the rest of the body for many months, indicates that this centre is in the neighborhood of that body.

If this centre exist, it is evident that irritation of a sensitive nerve after section at the border of the pons ought not to be followed by fall of temperature. In Dr. Wood's experiments the result was in agreement with this,—no fall of temperature under these circumstances following the most intense irritation of the largest trunk.

A knowledge of the existence of an inhibitory chemical centre throws a flood of light upon many hitherto inexplicable problems in clinical medicine. Thus, it has long been known that high bodily temperature may co-exist with any condition of the circulation, and as long as it was believed that the rapidity of the production of animal heat was directly dependent upon the activity of the blood-current, the co-existence of high fever and of lessened arterial action was a very strange phenomenon.

The mode of origin of an ordinary case of irritative fever now becomes evident. A boil, a pneu-

monic lung, or any local focus of irritation, sends its impulse up an afferent nerve to the inhibitory chemical centre, which is paralyzed, giving rise to the subsequent fever.

In another case the irritation may be of such a nature that the centre is excited to increased action, and the result will be, of course, universally lessened chemical movements, i.e., lessened heat-production and diminished bodily temperature.

This is completely analogous to what takes place in the case of the ordinary motor nervous system; the difference being that whilst in the former instance the result is a chill or a fever, in the latter it is a spasm or a paralysis.

Because, however, fever in some cases is produced by paralysis of the inhibitory nerve-centres, it by no means follows that it is always so; indeed, it is probable that there are other methods of its causation.

There may be an accelerator, as well as a depressor, of chemical activity in the body; and it is probable that there are certain poisons which elevate bodily temperature by a direct action on the tissues, since there are certainly substances, such as alcohol and nitrite of amyl, which lessen this chemical activity after the body has been separated from the upper nerve-centres by complete division of the cord, and which must therefore act directly upon the tissues or upon the blood.

ORIGINAL COMMUNICATIONS.

ON THE TREATMENT OF NEURALGIA BY THE CONSTANT CURRENT.

BY WHARTON SINKLER, M.D.,

Attending Physician to the Orthopaedic Hospital and Infirmary for Nervous Diseases.

IN the number of the *Philadelphia Medical Times* for July 15, 1872, I reported, together with some other cases of neuralgia, that of Mrs. P., who had suffered from neuralgia of the fifth nerve, which was relieved by galvanism. I will now give the further history of the case, and add other instances of neuralgia which have been treated by the constant current:

Mrs. P. returned to the Infirmary for Nervous Diseases* on August 26, 1872, with a renewal of her old malady. She states that she had experienced complete relief from pain from April until June 20. For several days she had been exposed greatly to wet, and had been occupied most of the day in a kitchen with a damp brick floor. On the day above mentioned she was suddenly seized, about 3 A.M., with an attack of pain in the left lower jaw, at the former seat of disease. Ever since then she has had one or more attacks of neuralgia each day. She had as many as six attacks, but occasionally a day would pass without any pain at all. For the past two weeks she has suffered more than ever, and has had almost constant pain in the jaw. Talking or eating will bring on an attack, but a draught of air against the face does not. She describes her suffering as being like a tearing apart of the jaw, and like running a knife along the bone. On the

* Hereafter, in this article, I shall, for convenience, use this title instead of the longer one.

day of admission she had had a severe paroxysm of pain, beginning about 4 o'clock A.M., and lasting about twenty minutes. Talking, however, always causes some pain, as do jars to the body. The jostling of a wagon which conveyed her to the railroad-station produced much suffering.

On admission, she was weak, for she could not take sufficient food, on account of the inconvenience in mastication; and she looked anxious and worn, and was restless. The gum of the left lower jaw was tender and swollen; the tongue coated and pasty.

She was ordered to have liquid food, and to take the emulsion of cod-liver oil and lacto-phosphate of lime. The battery was directed to be applied twice daily. For the first three or four days there was very little relief to the pain, except that for a short time after each application of galvanism she had ease.

A current from ten cells was used, one pole being placed on the nape of the neck and the other on the painful points along the jaw.

Six days after admission, the following note was made: She is decidedly better; has had no pain at night, and only two or three attacks yesterday. This morning early she had several attacks, but since the application of the battery she has had none. Her appetite is now good.

On September 11 she returned home, taking with her a sixteen-cell battery, which she had been taught to use. Her whole appearance had changed; she looked well and was cheerful. There was only an occasional slight twinge of pain.

On January 3, 1873, she wrote to say that she was very well, "and had grown portly." She had experienced several attacks of neuralgia from exposure to cold, but each time it was promptly relieved by the battery.

In this case, as in all others, we used a current so mild that it was scarcely felt; and from the first application the pain was always removed for several hours. Immediately after the sitting the tenderness of the gum had disappeared, and firm pressure caused no pain.

The direction of the current made no difference: whether it was passed from behind forwards (direct) or from before backwards (inverse), the result was the same.

Another case, in many respects similar to the preceding, is the following:

Case II.—Mary W., æt. 72, widow, applied at my clinic August 23, 1872. Has always been perfectly healthy. In March, 1872, she was exposed for some time to a cold wind, and the same afternoon violent pain began in the right side of the face, which continued all night, but lessened in severity towards morning.

For three months she suffered from this pain night and day. At times it would be a dull aching, and then there would be sharp paroxysms of pain. The point of greatest suffering appeared to be in the gum just below the right ala of the nose. Speaking or eating would generally bring on a painful spasm of the right side of the face. She had previously lost all of her teeth except four lower molars, and she now had these extracted, in the hope of relieving the pain. There was no ease from it, however; in fact, she thinks it was made worse. Finally she got somewhat better, but five weeks ago the pain came on with renewed violence.

Present state.—The pain begins at the point of emergence of the right infra-orbital nerve, and extends back along the upper jaw to the ear, and into and behind it. The whole of the alveolar process of the right jaw is tender. The suffering is continuous, but there are frequent attacks of tic douloureux. An exacerbation comes

on in the afternoon, without any chilliness, and continues throughout the night. In the early morning there is slight febrile reaction, and the pain moderates. Occasionally making firm pressure on the gum relieves the pain.

The patient suffers from indigestion after eating, and has nausea, with acid eructations. Her appetite is poor and her bowels constipated.

She has had various treatment, such as blisters behind the ear, electro-magnetism, and many local applications, but without permanent relief.

She came to my office daily for galvanic treatment for two or three weeks with fair regularity, and always experienced relief during the application and for a short time afterwards. But, having to be exposed to draughts of air and the jolting of the cars on her way home, the pain would soon return. It was therefore determined on September 16 to admit her to the hospital, and to use the galvanism twice daily. She was also ordered a hypodermic injection of morphia, gr. $\frac{1}{4}$, twice daily. The latter, however, had to be discontinued in a couple of days, on account of the nausea it occasioned.

Two days after admission it was noted that she was better, the pain not so severe, and the paroxysms of tic not so frequent.

The improvement steadily progressed, and on October 15 she was discharged, entirely relieved. The tenderness of the jaw had disappeared.

Mrs. W. remained free from pain all of the winter and summer following her discharge from the hospital. During the winter of 1873 she had an attack of neuralgia lasting two or three months, but not so severe as it had been before. A few days ago, October 31, 1874, I saw her: she stated that she had been comfortable all summer, but was suffering at the time from some pain in the jaw, caused by exposure to a cold wind a few days previous. There had been no galvanic treatment for two years.

The following case is scarcely a fair test of the efficacy of galvanism in neuralgia, as the patient had only four sittings; but I give it, as he declared he was always made worse by the application, and I wish to report the failures as well as the successful results from the use of galvanism. However, in the case of Mr. R., given below, the first two or three applications increased his pain, so that it is possible that had G. L. continued longer under treatment he might have been relieved. Niemeyer* tells us that "occasionally the pain is at first increased [by the application of galvanism], but that should not always induce us to stop the treatment."

Case III.—G. L., æt. 79, was sent to the Infirmary for Nervous Diseases by Dr. J. Ewing Mears, November 25, 1872. He first experienced an attack of neuralgia thirty-seven years ago. It came on three or four years after the death of his first wife, and was in the right jaw. It lasted twenty-three weeks, when he married again, and the pain left him.

While his second wife lived, twenty years, he had no neuralgia, but a few weeks after her death it returned again, and has not left him since. Ten years ago he had all of his teeth extracted, but it gave him no relief.

Present state.—The pain, which is constant, he experiences in both upper and lower jaw on the left side, in the branches of the inferior and posterior dental nerves, and occasionally in the infra- and supra-orbital nerves. In the latter it is very severe. The paroxysms of in-

* Text-book of Practical Medicine, vol. ii. p. 289.

tense pain come on every few minutes during the whole day. During a paroxysm the side of the face is screwed up, and he is unable to speak. There is never pain in the left side of the face.

He was ordered to have a current from ten to fifteen Callaud cells passed from the back of the neck to the painful points. After the first three applications he stated that the pain had been increased by each treatment. After the fourth he thought he was not suffering so much, but there was still considerable pain, and the attacks of tic were frequent. He did not return again, as he had determined to apply for surgical aid in the division of the nerve.

In this case an interesting point is the apparent influence that the married state had on the neuralgia. The disease made its appearance soon after the death of his first wife, ceased after his second marriage, and again began, after an interval of twenty years, almost immediately after the death of the second wife.

Case IV.—A. S., æt. 40, widow, has three children. She is healthy, and there is no evidence of syphilitic disease.

For ten or eleven years she has suffered from attacks of intercostal neuralgia, which is accompanied by pain in the supra- and infra-orbital nerves. She has had three or four attacks in the year, each lasting about two weeks. They have been growing more severe, and the last attack began three months ago. When she applied at the Infirmary for Nervous Diseases, January 17, 1873, she complained of pain in the left supra- and infra-orbital nerves and in the intercostal nerves on the same side. There was some palpitation of the heart, and a faint apex-murmur was heard. The pain never ceased entirely, but there were exacerbations. At times she felt chilly, and occasionally while the pain was severe the left side of the face flushed. There was an eczematous eruption on each side of the nose and over the malar bone. This she asserted disappeared when she had no neuralgia. During the severe paroxysms of pain she perceived a disagreeable odor in the left nostril.

Ordered galvanism daily,—the sitting to be of five minutes' duration. During the passage of the current through the head, both cheeks flushed.

After two applications the pain was no better, but the eruption was fading. On January 31 she had been steadily improving, and she then had only a slight dull pain in the upper lip. The patient entirely recovered, and has not been heard from since.

Case V.—Ellen W., colored, æt. 23, single, came to Dr. Mitchell's clinic at the Infirmary for Nervous Diseases, February 14, 1873. Was perfectly healthy until six years ago, when she began to suffer from pain in a decayed tooth. This lasted for three months, when she had the tooth extracted, but without relief to the pain. The pain seemed to be confined to the right lower jaw.

When seen, she suffered from an attack of pain about every five minutes. During the paroxysm the angles of the mouth and eye are drawn towards the ear, and all the muscles of the right side of the face twitch. She can bring on an attack by rubbing the face violently. The pain and spasm of the face are simultaneous.

The patient locates the pain in the lower jaw, and it seems to be intense, for during a paroxysm she bites the cheek until it bleeds.

There is a remarkable deposit of pigment on the right cheek, which began about three months ago. It extends from the ear to the median line of the chin over a space about one and a half inches wide. The cheek looks as if soot had been rubbed on it. Just in advance of the ear the coloration is very dark, and also

at the angle of the mouth and under the lip. There is no other change in the nutrition of the skin of the face. The girl is apparently of pure African blood. Ordered galvanism daily.

On March 7 she was much better, and the pigmentation was less marked.

March 17, she stated that the attacks were less frequent, and not so severe. The discoloration was decidedly fading.

Case VI.—J. R. R., married, merchant, æt. 45, was sent to me by Dr. S. W. Mitchell for galvanic treatment in June, 1873. Twenty years ago had a chancre, but has never had constitutional symptoms. Has had considerable anxiety about his business, but at present there is no mental strain. Four and a half years ago he had an attack of inflammatory rheumatism, and about six months later he was seized suddenly with pain in the right lower jaw. The pain came like a blow, and lasted five minutes. He was free from it for four weeks, when it began again, and lasted two months, being so severe as to keep him in bed all of that time. The pain gradually wore out, and he was then free from it for six months. A third attack came, and lasted four months, and the interval was only one month.

About February 1, 1872, an attack of neuralgia began, and did not cease until June of the same year. He then had no pain until January, 1873, when it began and lasted until he was seen by Dr. M. Since January he had not been free from the pain for one day, and the suffering had been intense.

Present state, June 28, 1873.—There are three points at which the pain is most severe: the emergence of the right infra-orbital nerve, a spot about the middle of the lower jaw, and the right half of the lower lip. There is also pain in the temple and right eyeball. In the latter it began to-day for the first time.

At the three points above mentioned there is no tenderness except during a paroxysm, when they all become sensitive to the touch, both outside and inside. There is also tenderness of the whole cheek during an attack, but it disappears with the paroxysm. There is constant dull pain in the face, but every few minutes there is an attack of violent pain which is accompanied by contraction of the muscles of the right side of the face. The mouth is drawn, and the eye tightly closed. The attack can at times be stopped by sucking the tongue against the roof of the mouth, but this sometimes fails, and nothing else shortens a paroxysm. Pressure does not relieve it.

The attack is brought on by talk, excitement, and some movements of the tongue, but not by eating or brain-work. Sight of right eye is bad. Hearing of right ear has become imperfect. There is no numbness or insensibility in the face. He suffers from indigestion and constipation.

The suffering he describes as horrible, and to alleviate it he takes morphia, gr. $\frac{1}{3}$, hypodermically, four or five times daily, but this gives him very slight relief, and he gets but two or three hours of sleep at night. Since the neuralgia first began he has lost sixty pounds in weight, and he is miserable generally.

At the suggestion of Dr. Mitchell, I began to use the galvanism twice daily. The positive pole was placed at the back of the neck, and the negative pole on the painful spots successively.

The current used was so mild as to be scarcely perceptible. The first two or three applications seemed to be followed by an increase of pain, and the patient was greatly discouraged. But on the third day the paroxysms of pain were certainly shortened and lessened in severity during the passage of the current. On the morning of the fourth day he informed me that he had slept nine hours the night previous, a thing that had not occurred for many months.

From this time improvement steadily progressed. The attacks of pain became fewer and of short duration. His nights were comfortable, and he was able to reduce greatly the quantity of morphia he took.

On July 11, after having been under treatment just two weeks, he was obliged to return to his home in the West. He took with him, however, a sixteen-cell battery, and wrote on February 7, 1874, saying that his improvement had continued. He had not become entirely free from pain, but the paroxysms were infrequent and unaccompanied by spasm of the facial muscles. He still continued to use the battery, and felt confident that he would eventually obtain entire relief.

This case is a remarkable illustration of the benefit that may be derived from galvanism in neuralgia. The pain had been atrocious, and everything had been tried for its relief without success; even division of the inferior dental nerve had been resorted to, and all the teeth on that side had been extracted.

The direction of the current made a decided difference. When the negative pole was over the foci of pain, it gave ease or checked a paroxysm; but an attack of pain was brought on by the inverse current; a strong current also increased the pain.

This patient never abandoned the use of morphia entirely, which, in the opinion of Dr. Mitchell, is essential to the success of galvanism in the treatment of such cases.

Case VII.—The notes of the following case have been kindly furnished me by Dr. Mitchell. Mrs. D., æt. 52. Neuralgia began in left side of jaw and the tongue in the winter of 1870. In the spring following she had eight teeth extracted in the lower jaw, and had ease until the next winter, when the pain returned suddenly. In the next summer she lost it, but in the fall it again appeared, and has not left her since.

Condition, April 24, 1874: The pain is in the lower jaw and left side of the tongue. At times, if exposed to cold, it is in the temple and just in front of the left ear. The pain is continuous, day and night, and is also paroxysmal. Talking and eating bring it on, and so do sweets in the mouth; salt and vinegar will also cause an attack of pain, but less soon. She has nausea at times, but no dyspepsia. Bowels constipated. The tongue feels as if scalded. When she is in pain the lips and gums are tender, but not the tongue. Eye-ground normal. An attack of pain can be checked by pressure in front of the ear. This fact—*i.e.*, that pressure at a remote point will sometimes relieve the pain in a nerve—has often been pointed out by Dr. M. in patients at the hospital.

In Cases I. and II. pressure over the painful points would always give a certain amount of relief.

Galvanism was applied to the painful points in Mrs. D.'s face on alternate days for two months, but without the slightest benefit. During this time arsenic was administered, and various other remedies were employed.

Case VIII.—J. W. B., admitted to the Infirmary for Nervous Diseases, January 26, 1874. He was 33 years of age, and married. Thirteen years ago he contracted a chancre, which was followed by secondary symptoms confined to the throat. Except an attack of intermittent fever, he has been perfectly healthy since childhood.

Four years ago, while passing his hand over the side of the face, he felt as if a thorn was sticking in the flesh at the angle of the nose. In about nine months

the pain began to run down to the angle of the mouth and back to the ear. The sensation about the ear was more of numbness than of pain. Matters continued thus, with intervals of relief for about half the time, until about four months ago, when the pain began over the right brow. The pain has been of a "flashing and darting" character, and has been worse lately.

All of the teeth in the upper jaw have been extracted, and some of the lower. No amount of pressure on the gum causes pain. There is a pustular eruption confined to the right side of the face. The eye-ground is normal, and there is no defect in hearing. The urine is normal.

The patient was ordered galvanism twice daily, and cod-liver oil.

The treatment was persevered in for two or three weeks, with relief to the pain in the supra-orbital nerve, but in the inferior dental the suffering was as great as ever. It was therefore determined to excise a piece of the inferior dental nerve. The operation was performed by Dr. T. G. Morton, one of the surgeons to the hospital, and, although there was no immediate relief to the pain, in time it was greatly mitigated. In a letter from him at his home in Sunbury, Pa., dated October 22, 1874, he says that he fears when cold weather returns the pain will be as bad as ever, for during a cold spell, a few days before he wrote, he had suffered considerably in the lower jaw. There had been no return of pain whatever in the supra-orbital. This is worthy of remark, for it was in this nerve that the pain had yielded to the galvanism.

Case IX.—O. R., æt. 35, was sent to me by Dr. Mitchell, Nov. 22, 1872. He had suffered from left supra-orbital neuralgia for several months, induced, he thought, by exposure to draughts of air. There was an eruption over the left brow, partly papular and partly pustular. When the pain was worst the eruption was most abundant. I used a galvanic current daily, placing the negative pole over the supra-orbital nerve, and the positive over one of the cervical vertebræ. Fowler's solution was also administered. Under this treatment the pain was entirely relieved, and, what is striking, the eruption disappeared with the neuralgia.

Case X. Sciatica.—Catherine A., æt. 33, married, was sent to me at the Infirmary for Nervous Diseases by Dr. W. H. H. Githens, with the following history. She had always been a strong, healthy woman, and had never had rheumatism. On June 23, Dr. G. delivered her, by the forceps, of a large child. There was considerable hemorrhage, but that was controlled, and she did well until the second day, when she was seized with violent pain in the right hip and posterior aspect of thigh. She had become chilled from exposure on the day previous, and ascribed her pain to this cause. The pain continued with great severity, shooting down the course of the sciatic as far as the knee, notwithstanding that anodyne applications were made freely.

On admission, she complains of pain, beginning in the right hip, and extending down the back of the leg to the knee. She is unable to bear any weight on the right leg, as it increases the pain, and, moreover, the limb is actually weakened. She is anæmic and weak, and her appetite is poor. Her bowels have been constipated, but she has taken medicine to relieve them. The lochia still persist. She sleeps badly and looks haggard. The pain usually grows worse in the afternoon and continues severe during the night; in the morning she has some ease. Pressure over the sciatic at any point causes pain.

She was placed in bed, ordered good food, and elix. ferri, quin. et strych., fʒi three times a day. The constant current was applied to the leg once a day. The positive pole was placed at the lower dorsal region of the spine, and the negative at various points over the

sciatic from its emergence to the popliteal space. The current from twelve to sixteen cells of a Stohrer battery was used, and the application lasted from ten to fifteen minutes.

The pain was speedily mitigated by these means, and the second night after admission she slept well. In two weeks she was allowed to get up, and could walk a few steps without much pain. She was kept quiet for some time longer, and in a few weeks was entirely well.

In sciatica, rest in bed is an important element in the treatment. In several cases treated at the hospital as out-patients it required a much longer time to effect a cure than in those patients whom we are able to keep at rest in the recumbent posture.

In addition to the cases above detailed, I could give several others; but the notes of them have been imperfect, or there has been other treatment used in addition to the electricity, which may have influenced the result.

Of these ten cases, five were completely successful, two were failures, and the remaining three were in a great measure relieved. Considering the severity of the neuralgia in every instance, the result is better, I think, than could be looked for under any other plan of treatment.

The effect of galvanism in relieving pain is very striking. Severe suffering often ceases after a few minutes' application of the current. Besides its influence on true neuralgias, many other forms of pain are cured by it; for instance, I have seen violent pain in the shoulder, in a case of hemiplegia, completely dissipated by the use of the current.

In Case V., the remarkable pigmentation of the skin at the seat of the neuralgia became greatly lessened under treatment. Dr. Anstie* refers to this action of galvanism, and states that he has seen "the constant current, in relieving facial neuralgia, not unfrequently disperse, almost instantaneously, the brown skin-pigment that has collected in the painful region,—i.e., near the orbit."

Electricity in the treatment of neuralgias is by no means a new agent, but it is only in the past few years that the constant current has been employed to any extent. The induced current has been used for many years, and with good results in a few cases, but often it failed entirely or aggravated the disease it was intended to cure. In the British journals a number of cases of neuralgia treated by galvanism have been reported, but in this country few if any have found their way into the medical periodicals; at any rate, I have not been able to find them, and it has therefore seemed to me well that I should detail my experience in this class of cases.

As to the method of applying galvanism, I have derived best effects from the current of a battery in which there is but little chemical action. A battery of Siemens-Halske or Callaud cells gives a current best suited for the treatment of neuralgia, but it is so bulky that it can be used only in the office of the physician. If a patient has to be treated at his own house, then we must use a portable arrangement of Smee or Bunsen cells. Some form of Stohrer's battery answers very well, but it is more of a "quan-

tity" battery than the Siemens-Halske, and causes more pain for the amount of electricity which is obtained.†

The current used should be mild,—from ten to fifteen "Callaud" or six to ten Smee cells. Niemeyer‡ speaks of active changes being produced in the skin, such as erythema and even blisters, at the points of application of the electrodes; but it is quite unnecessary that this should occur; in fact, the current need not be painful. Dr. Anstie states clearly that "only such a current is to be employed as produces a slight tingling and (on prolonged application) a slight reddening of the skin at the negative electrode."

The length of the sitting should not exceed ten or fifteen minutes; but it is of the greatest importance that the application should be repeated daily, and in many cases twice or three times a day is not too often to use the battery.

I have found that in most instances it makes but little difference whether the current be direct or inverse, and this is in accordance with the views of Dr. Anstie (*loc. cit.*), and also of Dr. Russell Reynolds.§ Eulenburg|| and Althaus¶ say that it is the positive pole which should be placed over the seat of disease, as the negative is too exciting; and Niemeyer, on the other hand, advises that in all instances the negative pole should be over the painful point. The truth seems to be that in regard to the direction of the current it varies in different individuals. In Case VI. the inverse current always increased the pain. This was frequently tested, and always with the same result.

In other cases the direct current produced pain, or it made no difference which current was used. This would seem to indicate that there was more than one variety of neuralgia. I shall not go into a discussion of the subject at this time, my object in this paper being only to point out to the profession the value of galvanism in relieving neuralgia,—a disease so terrible, and at the same time so difficult of cure.

The current should always be uninterrupted. Shocks or breaks in the current ought to be carefully avoided.

Dr. Weir Mitchell has obliged me by adding the following notes:

"Your paper on the usefulness of continuous currents in neuralgia tempts me to add some information as to the use of galvanism in cases of what I might call the neuralgic constitution,—a subject upon which, despite Anstie's admirable book, I have seen nothing said, there or elsewhere.

"This is what I mean by the neuralgic constitution. I know a few persons who are every now and

† When I speak of a "quantity battery," I mean one in which there is either a large surface of the elements or much chemical action, producing an amount of electricity capable of causing chemical decomposition, e.g., heating a wire red-hot. "Quantity is in proportion to the size of the elements; intensity is in proportion to their number" (Duchenne).

In a lecture on electricity in the number of this journal for Jan. 2, 1875, Dr. H. C. Wood, referring to "quantity" and "intensity," says (quoting Jenkin, "Electricity and Magnetism"), "these terms are remnants of an erroneous theory," and advocates the view of the same author that all galvanic currents have but one quality,—namely, strength, which depends on the internal resistance of the battery. All electricians, however, have not yet accepted this view.

then liable to attacks of neuralgia,—most often in the fifth nerve, sometimes in the arms, and more rarely elsewhere. I know of others who are liable to violent onslaughts of pain confined to a limited space, but which may come in almost any part of the body, but usually in the limbs. In two such cases, which were clearly not pre-ataxic neuralgia, the point of pain exhibited twitchings of near muscles, and also purpurial spots like bruise-marks. (See Report Col. Phys., 1872.)

“Some persons, and the cases are rare, exhibit only a remarkable tendency to neuralgia of the fifth nerve, and of this alone. The pain comes on after exposure to cold in winter, may attack any branch of the nerve, and fades out in summer. It does not seem, like the other forms, to be due to depressing causes, or to come, as they do mostly, in the spring. The most notable case of facial susceptibility to pain I have ever seen has been some time since dismissed cured. This lady, *æt.* 45, lives in the country, and four years ago was exposed to a severe cold, which froze the nose, ears, and cheeks. They were well and carefully treated, but ever since, a few minutes’ exposure to cold, whether dry or moist, inevitably brought on pain in some one of the exit-points of the branches of the fifth nerve. The attack after this followed the history of facial neuralgia. At the beginning there was often a slight chill, and, after a few hours, intense flush and relief. I treated her solely by galvanic currents applied to the exit-points, and through to the back of the neck. A week’s sittings brought ease. Two months’ treatment enabled her to face any cold with pleasure. The cure was absolutely perfect.

“Cases of general neuralgia—that is, of pain striking this or that nerve, and rarely of long duration—are sometimes due solely to a state of excited sensorium, arising from conditions of stomach, but even in these the far-distant pathogenesis lies usually in blood-losses, and the cases, as might be expected, are commonly females. Rest in bed for a month, with attention to the state of the stomach, injections of cod-liver oil, and systematic feeding, bring these cases into a condition in which it becomes worth while to resort to galvanism. Then I determine the localities most often infested by pain, and treat these points. I cannot say that I know how the currents do good, but in all probability they act not locally alone, but also on the related groups of sensorial ganglia in the centres. At all events, they surely serve some useful purpose.

“In all neuralgias we meet with cases rebellious to galvanism, and then I am disposed to suspect that there is some grave organic cause of pain, and to think nerve-section the proper remedy. The obstinacy of traumatic neuralgias is some support to this opinion, and neuralgias of stumps, for example, are usually amenable to but one remedy,—the knife. I may add that when the case has been well studied, and the point of section correctly chosen, section is usually a success; but the surgeons rarely pay enough of attention to the physiological conditions which must be borne in mind if we expect to attain good results.”

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

SERVICE OF DR. T. G. MORTON.

Reported by J. J. KIRKBRIDE, M.D.

PHOSPHORUS-NECROSIS OF UPPER MAXILLA—EXCISION.

H. M., aged 29, was admitted, October 28, 1874, with necrosis of the upper jaw. He was a match-dipper by profession, having been so employed since eleven years of age. His health has been moderately good until one year ago, when he suffered from a cough, with considerable debility, followed soon afterwards by toothache in the right upper jaw. Three months since, he had a tooth extracted which was much decayed, the dentist, according to his account, tearing away at the time a portion of the gum. During the next month three more teeth were removed at various intervals. Marked relief always followed these extractions, the patient returning to work the next day.

On admission, the right side of the face was much swollen and sensitive; all the teeth on that side were loose, up to the middle incisor, the gums being very boggy, swollen, painful, and perforated in many places, through which pus exuded in large quantities, while along the jaw dead bone was readily felt. The man had a full beard and moustache of considerable length, thus disproving the assertion that this appendage is a protection against the fumes of phosphorus. The patient was very anæmic, with a temperature of 97°. Lacto-phosphate of lime, and cod-liver oil, were ordered.

At the clinic, October 31, Dr. Morton removed all the necrosed portion of the jaw, the loosened teeth being first extracted; an incision was then made along the upper portion of the gum and roof of the month on the right side, and the bone separated front and back with the cutting-forceps.

But little hemorrhage followed.

Dr. Morton exhibited to the class a patient who had suffered from severe phosphorus-necrosis some years ago, contracted in the same manufactory as the former case; Dr. Hunt, in 1866, removed rather more than the entire half of the lower maxillary on the right side without making an external incision.

The supplemental jaw, which in 1867 was quite as large as the normal one, has since undergone great absorption, being one-third less than formerly; otherwise the patient has enjoyed perfect health, and has been ever since engaged in his former business as “match-dipper.”

VESICAL CALCULUS OF UNUSUAL SIZE AND WEIGHT.

Dr. Morton exhibited a specimen of vesical calculus which had been removed after death by Dr. Elwell, of Vincenttown, N.J., from the bladder of a man, aged 65, who had been suffering from vesical irritation and all the symptoms of stone for twenty years previous to his death. The patient would never consent to any examination of his bladder. Death took place from exhaustion. The stone resembled a medium-sized white potato, and is of the phosphatic variety. It measures eight and three-fourths inches in its longest dimensions by six and a quarter in circumference, and weighed, immediately after its removal from the bladder, seven ounces four hundred and twenty grains.

PHOSPHORUS HYPODERMICALLY. — In Dr. H. C. Wood’s wards in the Philadelphia Hospital phosphorus has been given hypodermically in a number of cases; two to three drops of the oleum phosphoratum (Prus. Pharm.) being given in eight to ten drops of glycerin. No serious local irritation was produced in any instance.

TRANSLATIONS.

HYSTERICAL ATTACK IN A MAN CURED BY COMPRESSION OF THE TESTICLES.—Dr. P. Foet relates the following case in a letter addressed to the editor of the *Gazette Hebdomadaire*: Some days previously he had been called to attend a certain M. Chartres, who, it was said, was suffering from an attack of apoplexy. Arriving at the patient's bedside, he found him lying on his back, the head turned to the left, the face of a natural color, the eyelids partly closed, the mouth open, but no frothing. The respiration was slightly accelerated and noisy. There was tympanitis. The patient appeared unconscious, and did not reply to questions. From time to time he carried his left hand to his throat, as if to rid himself of something oppressive. The right side was not paralyzed; there were no reflex movements. Sensibility was absent over the whole body. The pulse was small and rather quick.

On attempting to ascertain whether the pupil was contracted, the patient's face became flushed, the eyelids trembled continuously, the teeth chattered, the neck became swollen, and the arms and legs were seized with such violent convulsive movements that three strong men were required to hold him. The respiration became still more rapid, even anxious.

At this moment Dr. Foet compressed the patient's testicles firmly, and in less than a minute the attack had completely disappeared. There only remained a slight stupor, lasting for the space of about an hour. Dr. F. learned afterwards that the man was quite irritable; that on the day previous he had been very "contrary," and that all that day he had experienced a fixed pain in the right temple, which he had compared to that which would be caused by a nail being driven into the head. He had been subject to these pains, as well as to occasional general attacks of pain in various parts of the body. Some moments previous to his attack, he had felt great lassitude, with incessant yawning, and had lain down, thinking that they would disappear. He had had such attacks many times before, but had never lost consciousness. He remembered the events of the day, but vaguely, and replied to a question put to him by Dr. F. when, to the bystanders, he seemed entirely unconscious. Titillation of the palate and half-arches showed complete insensibility.

An antispasmodic was prescribed, and the next day the patient returned to his work. At the conclusion of his letter Dr. Foet asks the question whether the disappearance of the attack was due to the compression of the testicles in itself, or was not rather due simply to the pain which was thus caused. He inclines to the latter hypothesis.—*Gaz. Heb.*, December 11, 1874. X.

CHANGES IN THE RADIAL NERVE RESULTING FROM LEAD-POISONING.—The radial nerve of a patient who had died suddenly while under the influence of lead-palsy showed a normal appearance and volume, and, after isolation, normal medullated fibres. No trace of fatty degeneration.

After hardening in bichromate of potassium, sections stained with carmine showed on microscopic examination, instead of the usual yellow medullated filaments, which were decidedly diminished in number, certain faintly-dotted red spaces. The latter, composed of small circles arranged in groups, showed with higher powers sharp contours, and were evidently cross-sections of the filaments of which the bundle was composed.

In the centre of these circles certain dark-red points could be seen, which were probably sections of axis-cylinders, so that the sections were such as are found, for instance, in the sympathetic, which Remak, Nau-

mann, and Eichorst have shown to be regenerating nerve-filaments.

As in the cases examined by these observers, so also in the present case the trunk of the nerve showed more of these filaments than the branches.

Paralysis of the radialis by lead-poisoning would thus appear as primarily an affection of the nerve-trunk. The spinal cord and the proximal fibres of the cervical plexus were found healthy.—*C. Westphal. Centralblatt*, No. 56; from *Archiv für Psychiatrie*, etc., 1874, iv. 767, 783. X.

THERAPEUTIC NOTES.

TREATMENT OF SACCHARINE DIABETES BY PHENIC ACID (Dr. Heanjo: *Gaz. Med. de Bahia*, July, 1874).

—A celebrated professor of music of Bahia, Sr. Bispo da Igreja, fourteen years ago, while riding along a country road near that place, was struck upon the back by a falling tree, and was thrown from the saddle violently to the ground. After much suffering, and a long and careful treatment, he recovered his health so as to be able to follow his profession. Ten years after this, he began to feel ill, and placed himself under treatment. He had intense thirst, a constant desire to urinate, loss of appetite, a dry, rough skin, general debility, and total inability to perform mental work. Trommer's test repeatedly showed the presence of glucose in large quantities in the urine. For four years he was subjected to salt baths daily, and an appropriate and rational treatment, without much amelioration of his condition.

Phenic acid, as recommended by Ebstein and Müller, was then prescribed according to the following formula:

R Acidi phenici cryst., gr. xvss;

Aq. menthæ pip.,

Aq. destillatæ, aa f3i.—M.

Sig.—Take one-sixth part morning and evening.

The patient was permitted to select his own diet, but was cautioned against excess. In three days the polyuria and polydipsia had notably diminished, along with the amount of sugar in the urine, and the bodily and mental tone were much improved. By the continued use of the medicine, the professor gradually lost all his afflictions and began to grow fat. The last to vanish was the sugar in the urine. At the end of three months it could no longer be detected by the test. The patient still continues to take the medicine, though there is probably no longer any need to do so. He is apparently in perfect health, and is engaged in the active pursuit of his profession. W. H. WINSLOW.

CHLORAL IN SEA-SICKNESS.—Dr. Giralde (*Jour. de Thérap.*) has found that chloral is very efficient. Before crossing from Calais to Dover in rough weather he had a draught made up composed of chloral, forty-five grains; distilled water, one and a half fluidounces; gooseberry syrup, two fluidounces; French essence of peppermint, two drops. He took half of the draught as the vessel left the harbor, and arrived at Dover without having suffered in the least from sea-sickness, whilst his companions were in the usual condition of prostrate misery.

POWDER FOR CORYZA.—

R Bismuth. subnitrat., ʒii;

Pulv. benzoini, ʒi;

Morphiæ muriat., gr. i.—M.

Div. in chart. No. ii.

One to be used as snuff in the course of the day. The insufflation of tincture of iodine and even of ammonia may be found useful in certain cases; but the latter should be used with caution, for fear of provoking epistaxis.

PHILADELPHIA MEDICAL TIMES.

A WEEKLY JOURNAL OF

MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, JANUARY 30, 1875.

EDITORIAL.

BLUE LIGHT IN THERAPEUTICS.

SOME few years ago, General Pleasanton, of this city, created quite a stir in circles that should have judged more critically, by his experiments upon the effect of keeping animals and vegetables under blue glass. He asserted that blue light has a most marvellous effect upon all forms of life, and his views were received with a good deal of favor. They even found practical advocates in our profession, so that blue glass and blue paper made their way into hospital wards, and very great therapeutic value was even attached to them by some physicians. Recently our attention has been called to the subject by an elaborate and laudatory paper on the medical use of blue light, in one of the homœopathic journals.

It is a very curious circumstance that all the writers and experimenters believe that there is an active virtue in blue light, and that a person under blue glass gets more of this blue virtue than does a person upon whom nature's sun shines unobstructed. A moment's consideration ought, however, to teach the veriest tyro in science that the blue glass does not add anything to the sun's ray, but only takes away from it. The light beneath the blue glass is blue not because the glass has altered or colored it, but because the glass has obstructed the passage of the other rays of the spectrum, and has allowed the blue to pass

alone. A man in the hospital ward gets the same amount of blue light on him whether colored glass be there or not. To attribute active therapeutic powers to the colored light is therefore, scientifically speaking, foolishness.

We have also failed as yet to discover any good grounds for believing that light as made by the Creator contains anything deleterious to life, or that it can be improved artificially. The gentleman previously alluded to did seemingly show that the pigs raised under blue glass were finer than those of the same litter who had shared the common lot of their brethren, and did certainly raise very large crops of grapes in greenhouses into the roof of which blue glass had been placed. As we are under obligations to him for great courtesy, we are sorry that scientific candor forces us to state, after careful examination of his experimental procedures, that in them he violated the primary canons of scientific experimentation, and that his results are really of no value.

We saw the two sties, with their pigs. The "blue sty" was large and clean, airy and dry, with a few blue panes here and there in its roof; the other sty was exposed, dirty, and wet. The pigs in the "blue sty" got practically as much daylight as did the others, only the magic blue light once in a while crossed their pathways. The result, to our mind, simply showed that pigs, like their ilk even among mortals, are amenable to the beneficence of hygiene.

It is hardly worth while to say a word about the grapes, since there were no comparative results. A magnificently-situated grapery, under-drained in the most expensive and scientific manner, with a deep, rich compost-bed, in which vines of the most approved character were planted and tended by a skilful gardener, of course yielded large crops of grapes.

It was four or five years ago that we made the inspection, but, if our memory be correct, the blue lights constituted only one-third or less of the roof, so that the grape-vines were not deprived of other light.

Of course, we are open to conviction upon any scientific subject, but, if there be any truth at all in the doctrine of evolution, life must have adapted itself in the course of the last — millions of years to light as it is, and experiments to disprove this, in order to be convincing, must be conducted by those who appreciate the difficulties and necessities of scientific experimentation: certainly the burden of proof lies very heavily upon any one who attempts to improve sunlight.

CONCOURS.

THE Faculty of Rush Medical College, Chicago, has just held a concours to select a lecturer on obstetrics in the spring course. Ten gentlemen applied, and were allowed a week to prepare a lecture on assigned subjects. Four were then selected out of the ten candidates, according to the merit of the lectures, and each of these four subsequently drew a subject out of a hat and proceeded to lecture forthwith. The successful competitor was Dr. E. W. Sawyer. We have nothing but praise for any attempt to do away with the "grandmother system" of selecting medical professors, but we cannot refrain from calling attention to the fact that the "concours" does not take into sufficient account originality. The world may lose the good work the original medical thinker would have done if placed in a professorial chair, simply because his "gift of the gab" is not equal to that of his more fluent but more superficial and less original competitor.

A true system of choice would take into consideration the highest ability, that of doing original work, as well as the lower ability, that of speaking well. It seems to us that a better plan than the ordinary "concours" would be for the candidates to lay before their judges the work they have accomplished, and then proceed to lecture; the final judgment being made after a careful consideration of the whole field.

PROCEEDINGS OF SOCIETIES.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

THE PRESIDENT, DR. WILLIAM PEPPER, in the chair.

THURSDAY, DEC. 10, 1874.

REPORT of Committee on Dr. Hodge's Specimen.—The committee appointed to examine the specimen presented by Dr. Hodge at the meeting of the Pathological Society held September 23, 1874, report that they have carefully examined the specimen, and find that the tumor was an ovarian tumor attached to the broad ligament by inflammatory adhesions.

H. LENOX HODGE,
J. EWING MEARS,
JOHN S. PARRY.

1. *Excision of the Knee.*
2. *Cystic Disease of the Submaxillary Gland.*
3. *Cyst of the Temporal Region.*
4. *Supernumerary Toe.*

Dr. JOHN ASHURST, Jr., presented the specimens, with the following descriptions: The parts exhibited were the condyles of the femur, the articulating surface of the tibia, the patella, and the remains of the semilunar cartilages. The specimens were exhibited in their recent state (the operation having been performed that morning), as furnishing an excellent illustration of the gelatinoid change which Brodie had described under the name of pulpy, and Swain under that of gelatiniform de-

generation. The affection was called by Barwell *strumous*, and by Athol Johnstone *scrofulous synovitis*; but Dr. A. preferred the name *gelatinous arthritis*, because, while originating in the soft tissues, the disease, if not interfered with, ultimately involved all the structures of the joint. The patient from whom the specimens on the table were derived was a boy about five years of age, who had suffered from the disease nearly two years.

Dr. JAMES TYSON inquired of Dr. Ashhurst whether the "gelatiniform degeneration" here referred to was not, more precisely speaking, an example of the so-called *mucous degeneration* of the pathologists, of which the essential feature was a conversion of the intercellular substance into a transparent mucin-containing material, while the cells themselves remained intact. The seat of the changes in the specimen presented would seem to be that especially selected for this degeneration, *i.e.*, the cartilages and bones.

Dr. ASHURST replied that, so far as he knew, no one had investigated the minute anatomy of this disease except Mr. Barwell, who regarded the condition as essentially the same as the granulation-change met with in ordinary inflammation. The terms *gelatiniform*, *pulpy*, etc., etc., Dr. A. thought referred to the naked-eye appearances of the parts, rather than to their microscopic characters.

2. *Cystic disease of the submaxillary gland.*—The specimen consisted of a much hypertrophied submaxillary gland, exhibiting at its posterior part a large cyst which contained a whitish mucoid substance. The gland had been removed by excision twelve days previously, from a lad thirteen years old, who had been suffering from the affection between four and five months. Excision rather than simple incision was employed, as being a more rapid as well as more radical method of treatment, and one the better results of which justified the slightly greater risks by which it was attended. The operation had presented no particular difficulty, the facial artery being the only large vessel which required division, and the patient was since convalescent.

3. *Cyst of the temporal region.*—This cyst, which belonged to the *cutaneous proliferous* or so-called *sebaceous* variety, had unusually thick walls, and was readily removed, by enucleation, from a boy about ten years old.

4. *Supernumerary toe.*—This was removed from an infant of eight months. The deformity affected the left foot only, the superfluous digit growing inwards from near the base of the great toe.

Keratosis Obturans (Wreden).

Dr. CHARLES H. BURNETT presented the specimen, and read the following paper:

"I desire to call the attention of the Society to a specimen of obstructive disease of the external ear, recently described by Wreden, of St. Petersburg, and named by him *keratosis obturans*, in contradistinction to *ceruminosis obturans*, with which it has often been confounded, though differing from it very widely.

"The latter disease, as its name implies, consists of a mass of inspissated cerumen, but it is easily removed by appropriate syringing, and the ceruminous nature of the mass removed from the ear is recognized, among other features, by the rapidity with which it dissolves in water.

"*Keratosis obturans*, however, recently tabulated by Wreden as a separate and special disease of the ear, is a collection of epithelial laminæ, derived from the cutis of the external auditory meatus, of gradual accretion, causing great deafness, and very obstinate in its resistance to removal.

"Every one who has had any extended experience in removing impacted masses, usually of cerumen, from the ear, must have remarked the fact that now and then

a mass is encountered requiring a piecemeal removal by the patient use of syringe and forceps, and which, after lying a long time in water, will not dissolve as ordinary wax of the ear does. It is such exceptional masses that Wreden has investigated, and, finding that their composition is not of cerumen but of the horny elements of the cutis, he has proposed for them the name of *keratosis obturans*.

"These obstructive bodies are not confined to any age or sex.

"Wreden states that his attention was first specially called to their peculiar nature by meeting a very adherent one in the ear of a little girl. In this case he was so fully impressed with the suspicion that he was dealing with a wad of soft white paper maliciously placed in the ear by the young patient, that he accused her of the deed, and, although she denied it, he was not convinced of the truth of her denial until the microscope revealed the fact that the mass he had with great difficulty removed was composed of epithelial elements arranged in peculiar laminae.

"Upon inspection of the ear containing such a mass as I have described, a thin layer of ordinary cerumen may be seen covering the outer surface of the plug, and thus one may gain the impression that the case is one of ordinary ceruminosis obturans or ceruminous impaction. But continued syringing, by its barren results in such cases, soon convinces the operator that the obstruction is no ordinary one.

"The case furnishing the specimen I exhibit this evening came under my care last July. The patient was a gentleman sixty years of age, suffering with intense deafness and tinnitus in the occluded ear, and, owing to the fact that the meatus was rendered abnormally tortuous by two large exostoses of the meatus, one above, the other below, it required patient and careful picking and syringing for a half-hour for eight days before all the foreign body was removed, with, at last, a restitution to normal hearing. From statements of the patient I inferred that similar though smaller and less annoying plugs had been removed from the ear, though he could not give any idea as to the length of time the present one had been forming, as the onset of deafness was almost instantaneous.

"Usually, in these cases of keratosis in the external ear, no part of the mass comes away as a coherent plug, but the mass must be broken down and removed in small pieces. In this case, however, I was fortunate enough, by the use of a solution of bicarbonate of soda (gr. x ad f̄ij) in glycerin and water, to remove about half of the mass as a whole. When it was first washed out it was perfectly white, and resembled a set of layers of wet tissue-paper slightly separated from each other by the buoyant effect of the water. When pressed upon it felt quite as hard as it does now, but by this time the color of the plug has changed from white to light brown.

"Any one pressing upon this mass will perceive how readily its peculiar resiliency distinguishes it from the ordinary cerumen-plug, with its soft and greasy consistence.

"As insolubility of the removed mass is one of the distinctive features of this peculiar aural disease, I have allowed this mass to remain constantly in water and glycerin since its removal from the ear last July, and the result of the experiment may be seen at this time.

"Its resistance to solution and its leathery consistence will readily account for the difficulty one experiences in removing it from the ear.

"Wreden has not suggested any cause for the occurrence of this disease of the ear, and, although among the laminae composing these masses he has sometimes found vegetable spores, he is not inclined to ascribe the origin of the mass to irritative presence of a fungus in the auditory canal.

"In cases where a tendency to recur is fully established, care in preventing an accumulation of the laminae will greatly simplify the malady as well as the treatment."

Cancer of the Cæcum, and Intussusception into Large Intestine—Intramural Fibroid Tumor of the Uterus—Cystic Ovaries.

Dr. WHARTON SINKLER presented the specimens, for Drs. J. J. BLACK and STEWART, of Newcastle, Delaware. They were derived from a lady who was in her sixty-third year, and previous to September, 1873, was remarkable for her good digestive powers. After that time she was subject to flatulence, with severe attacks of pain in the abdomen, which increased in frequency as her strength failed. For three months before the close of life, vomiting was a prominent symptom, being induced by every attempt to take nourishment, and for the last ten days she was kept alive by the repeated exhibition of brandy, a large portion of which was rejected.

She died October 18, 1874.

The post-mortem examination was made the following day by Dr. Black, in presence of Drs. Porter and Bush, of Wilmington, and Dr. Stewart, of Newcastle.

The specimen of bowel included the large intestine from the commencement of the colon. Dr. Black wrote that the first part of the transverse colon appeared to have "swallowed" the caput coli, the appendix vermiformis and commencement of the ileum being also carried in, while the cæcum appeared to be a mass of cancer. On opening the first part of the transverse colon, this mass seemed to lie within it, mucous surface to mucous surface, and peritoneal to peritoneal.

The mesentery and omentum were full of shot-like bodies, and the duodenum up to the pylorus was very much thickened, and contained the same deposit almost blocking it.

The kidneys were slightly granular; the liver of natural size,—smooth, but hardened in texture, of light-brown color, and somewhat fatty. The uterus contained the intra-mural uterine fibroid forward, which was the seat of a calcareous degeneration. The right ovary contained a cyst as large as an orange, filled with fluid; the left, a similar smaller cyst.

The specimens were referred to the Committee on Morbid Growths.

Clot in Left Corpus Striatum.

Dr. WILLIAM DARRACH presented the specimen, derived from a male patient aged 53 years, height five feet eight inches, stout, of sanguineous temperament and of intemperate habits, but always able to walk.

On November 28 he had an attack of apoplexy, which produced paralysis of the right arm; he was unconscious, breathed heavily, and cold perspiration stood over the face; his nose was cold, and back of the head hot; pupils contracted; no strabismus. Pulse very feeble. Ten ounces of blood were taken by cups from the occipital region. The pulse came up after the bleeding, and consciousness was restored several hours after. The following morning he was able to swallow, and talked rationally, and the right arm was raised to his head.

November 30, 4 P.M.—Unconsciousness again returned, with all the other symptoms. Cups were again resorted to, and, after much suction, the blood flowed. Eight ounces were again taken. The following morning the consciousness returned, and he was enabled to take brandy and beef-tea as before.

December 1, P.M.—The congestion again returned, with the former symptoms. He was again cupped, with great difficulty, as the blood was very thick, but he was again relieved.

On December 2, A.M., he was unconscious; became worse in the afternoon, and the left arm also became

paralyzed, but there was no paralysis of the lower extremities. He passed water with great force. At this stage it was not thought advisable to renew the cups, and death followed after midnight.

Post-mortem.—*Heart.*—Right ventricle covered with fat. Left ventricle quite firm. Aorta showed an atheromatous condition.

Liver.—Fatty degeneration manifest.

Brain.—Sinuses engorged with blood. Pia mater cloudy and cedematous.

Left lateral ventricle contained a very large clot in the corpus striatum.

In the right none was perceptible, although there had been paralysis of the left arm the last day of his life.

The arteries of the base of the brain were markedly atheromatous.

BIOLOGICAL AND MICROSCOPICAL SECTION OF THE ACADEMY OF NATURAL SCIENCES.

JANUARY 4, 1875.

DIRECTOR W. S. W. RUSCHENBERGER, M.D., in the chair.

DR. J. GIBBONS HUNT made a very interesting verbal communication upon the subject of *amplifiers for the microscope*, in the course of which he remarked that from the time of the first observation by the aid of more than two convex lenses, an almost constant effort had been made by opticians to fit in the best intermediate glasses, and yet further improvement in this respect was confidently to be looked for. The amplifier which he had upon the table consisted of a concavo-convex lens, with its concave side turned towards the eye, and so placed within the body of the microscope as to stand at a considerable distance from the objective. This adjustment of position was best accomplished by having the amplifier screwed to the end of a tube arranged with rack-work in such a manner as to traverse six or eight inches, because we could thus compensate for a want of complete correction in the objectives employed.

The advantages obtained by using an amplifier were, in the first place, gain in magnifying power, as could be seen in his microscope upon the table, when with an amplification of only 1800 diameters, afforded by a $\frac{4}{10}$ of an inch objective, he had on exhibition the *Navicula angulatum* resolved into dots all over the field, which was apparently more than sixteen inches across. By the aid of an amplifier we also gain a greater focal distance, and an increase of flatness of field.

Amplifiers have been employed in telescopes for the past fifty years, but ten or twelve years ago they were only adapted to microscopes, in this city at least, by one or two amateurs. Subsequently, Mr. Tolles, of Boston, saw them in use here, and on his return home made one, apparently with gratifying success, as he has since kept them in stock. Some few years since, Mr. Dickinson, of New York, wrote a paper upon amplifiers, claiming that by their aid he could obtain a power of 100,000 diameters; but objects thus magnified are visible only as dim shadows, similar to those shown by the solar microscope, quite unfit for data in scientific work. Such amplification, however, may be employed upon diatoms, the resolution of which does not require definition.

Dr. J. G. RICHARDSON inquired of Dr. Hunt whether, in his opinion, the $\frac{4}{10}$ objective associated with his amplifier, as he had it upon the table, and eye-pieced so as to give a power of 800 diameters, was equal to his Powell and Leland's $\frac{1}{18}$ immersion lens, combined with the "A" eye-piece.

Dr. HUNT replied that on histological work the

results were not quite so good, but on *Pleurosigma angulatum* he considered them fully equal. The combination of amplifier and objective which he used was, however, a merely accidental one, so that a skilful optician would probably be able to arrange the lenses more efficiently, and thereby enable microscopists to obtain this greater amplification at a much lower cost, and yet with definition good enough for scientific work. Mr. Pigott's aplanatic searcher appeared to be a modification of the amplifier, but had proved so unsatisfactory in his hands that he had entirely laid it aside.

Dr. HUNT also exhibited a beautiful specimen of the *Protococcus nivalis*, or Red Snow, which he believed had been discovered for the first time within the United States, by Mr. Harkness, of California, who found it growing upon the Sierra Nevada Mountains. For a long time it was a matter of dispute whether this organism belonged to the animal or the vegetable kingdom; but from observations made upon specimens brought from the polar regions by Captain Parry in 1815, and which grew in bottles of snow, its vegetable nature had been demonstrated. In the growing stage, this plant is of a green color, and it is only the resting spores which present the brilliant red hue from which it derives its name. Dr. Hunt stated that on examining portions of the *Protococcus nivalis* under the micro-spectroscope he had found that its coloring-matter entirely blotted out the violet end of the spectrum, leaving the red, yellow, and orange untouched.

Dr. J. H. MCQUILLEN showed a specimen of muscular fibre from the sheep, which, after the simple method of preparation of allowing it to remain between two of his own teeth for five hours, he had placed in glycerin and teased out with mounted needles, thus obtaining a magnificent view of the ultimate fibrillæ of the muscle.

Dr. J. G. RICHARDSON exhibited a fine specimen of a vertical section from the mucous membrane of the tongue of a calf mounted in balsam, which at his urgent request had been loaned to him from the Army Medical Museum. He desired to call the attention of members to the fact that each individual epithelial cell, throughout almost the whole thickness of the membrane, displayed its outline and nucleus with perfect distinctness, and that, therefore, the statement made when balsam preparations were last under discussion, that they showed hardly anything, was inaccurate.

Dr. J. G. HUNT exhibited a similar specimen of his own, mounted in glycerin, and remarked that, when thus prepared, the epithelial cells were displayed, not shrunken, *but of their full size*, and that those important elements, the connective-tissue fibres, were clearly visible, instead of being lost to view as in the balsam preparation.

Dr. RICHARDSON observed that even if the *fresh* glycerin preparations exhibited these delicate fibres more plainly, yet the specimen preserved in balsam displayed the muscular-fibre cells with far greater distinctness, and the absolute permanence of objects mounted by the balsam method constituted one of its most important recommendations.

Dr. H. C. WOOD, Jr., stated that the glycerin preparation appeared to be superior to that mounted in balsam, and moved that in order to settle this question, about which there had been so much dispute, these specimens should be referred to a committee composed of Drs. J. H. McQuillen and James Tyson, for examination and report.

Dr. J. G. HUNT exhibited an exquisite specimen of the liver of a common fly, showing with remarkable clearness the arrangement of the hepatic cells and ducts, and stated that he proposed mounting a series of preparations displaying the structure of the liver from its simplest form in the articulatæ up to its most complex arrangement in the human organism.

REVIEWS AND BOOK NOTICES.

A PRACTICAL TREATISE UPON ECZEMA, INCLUDING ITS LICHENOUS AND IMPETIGINOUS FORMS. By DR. MCCALL ANDERSON, Professor of Clinical Medicine in the University of Glasgow, Physician to the Royal Infirmary, to the Dispensary for Skin Diseases, and to the Cutaneous Wards of the Western Infirmary, etc. Glasgow. Third Edition, with Illustrations. Philadelphia, Lindsay & Blakiston, 1875.

The contributions to dermatology which Dr. Anderson has given to the profession during the last ten years, although by no means voluminous, are of such a character as to be appreciated and valued by all who have occasion to study this class of diseases. The treatise upon eczema, of which we now have a third edition, was the first of a promised series of monographs upon the various diseases of the skin which it was the intention of the author to write, but which, unfortunately, have never been completed beyond "Diseases of Parasitic Origin," and "Psoriasis." His work upon Eczema is, without question, the most complete, satisfactory, and practical exposition of this disease which we possess, affording a clearer insight into the subject than is to be obtained from any other volume. The disease is one which has to be observed and studied in its entirety in order to comprehend it thoroughly, and it is precisely in this particular that Dr. Anderson succeeds so admirably, presenting, as he does, in his essay, a complete picture of this protean affection. Space forbids entering into the subject matter of the book, but we take great pleasure in commending it to all those who desire to obtain a knowledge of the disease and its proper treatment. It may be added that this latter subject, the treatment, as given by the author, will be found to be especially valuable to American readers, inasmuch as the views expressed coincide so entirely with the experience of certain institutions in this country where many examples of this disease annually receive care.

L. A. D.

OUTLINES OF THE SCIENCE AND PRACTICE OF MEDICINE. By WILLIAM AITKEN, M.D., F.R.S., Professor of Pathology in the Army Medical School, Corresponding Member of the Royal Imperial Society of Physicians of Vienna, etc., etc. London, Charles Griffin & Co.; Philadelphia, J. B. Lippincott & Co., 1874. Pp. 593.

In taking up this handsome volume, two important questions immediately suggest themselves,—viz., first, are not such abstracts unworthy of countenance and support, on account of their tendency to make superficial students of medicine? and secondly, admitting, for the sake of argument, that a well-arranged epitome of practical medicine is needed, have we such an example of condensation in the pages before us? We confess to a strong feeling of anxiety on the score of the abstract value of such guide, originating in the well-known circumstance that medical students are only too apt to seize with avidity any excuse for neglecting that thoroughness, or "Grundlichkeit," which should be a *sine qua non* to their entrance into our profession. Nevertheless, if, by amplifying and elevating the standard of final examinations, the use of this book could be restricted as prescribed by its author, namely, to the duty of serving as "a clinical guide and companion [to the student] in the wards of the hospital, and an aid to his memory in the lecture-room," we believe benefit, instead of injury, would arise from its employment. We would, however, indelibly impress upon the minds of all the mournful fact that dark shades to these outlines will be filled in by any and every novice who dares to take into his hands the issues of life and death

without more complete preparation than the work under consideration would alone enable him to obtain. But, granting that under proper restrictions compendiums are not unmitigated evils, we can honestly recommend this one as an excellent epitome of the essentials of the science and practice of medicine, admirably calculated to lead a true student to more thorough investigations of the subjects whereof it treats. The arrangement and general plan of the book are similar to those adopted in the author's larger work, as well as others of its class. We notice, however, some important improvements, among which the systematic prominence given in the opening chapter (all too brief as they are) to *general*, and, later in the book, to *special* pathology, as well as the method of providing careful guides to the clinical investigation and diagnosis of diseases affecting the various systems and groups of organs, are worthy of especial praise.

Of course, in such an extended work the author has not always succeeded in sifting out the most important facts, and occasionally his process of selection has been carried to an injurious extent. For example, we think that even first-course students should be taught on page 545 that oxalate of lime occurs as a urinary sediment, especially when the existence of oxaluria is recognized on page 548; and we can imagine the bewilderment of a tyro who is instructed on page 541 to administer a quarter of a grain of "morphine" as the equivalent of half a grain of solid opium or twelve drops of laudanum every hour for the relief of a "gall-stone colic." The typographical appearance is good, but the proof-reading seems to have been less careful than is customary in books printed in America, numerous misprints being overlooked, as, for instance, "aconium" for "aconitum" on page 96, and the ludicrous blunder of "diet" for "meal" on page 550. J. G. R.

GLEANINGS FROM OUR EXCHANGES.

ESMARCH'S BLOODLESS METHOD (*New York Medical Journal*, January, 1875).—Dr. J. B. Sands reports the results of one hundred and forty-three bloodless operations performed at the principal New York hospitals.

There were sixty-three amputations, excluding those of the fingers and toes. Of these, forty-four were primary, for injury, and nineteen secondary, or for disease. Of the primary amputations, ten cases, or 22.7 per cent., terminated fatally,—the causes of death being the following: pyæmia, four; exhaustion or shock, three; spreading gangrene, one; erysipelas, one; hemorrhage, one.

Of the cases fatal from pyæmia, one patient had the disease at the time of the operation.

Of eight cases of primary amputation of the thigh, two cases, or 25 per cent., ended fatally.

Of eleven cases of primary amputation of the leg, three cases, or 27.3 per cent., were fatal.

Secondary amputations, nineteen cases, give a mortality of 21 per cent. The causes of death are stated as follows: tetanus (existing at time of operation), one; exhaustion, one; phthisis, one; pyæmia, one.

Out of fourteen cases of excision of the joints, only one proved fatal; the cause of death being pyæmia. The list included two more deaths, one following an operation for necrosis,—the only fatal case out of thirty-six,—and the other an operation for the ligation of the ulnar artery, performed for a wound near the wrist.

CASE OF NORMAL OVARIOTOMY (*New York Medical Journal*, January, 1875).—Dr. T. T. Sabine reports the case of a female, æt. 25, who was perfectly well up to eight years ago, at which time, while menstruating, she took a cold bath, which was followed by cessation of

the menstrual flow, and a very severe attack of neuralgic pain in the left iliac fossa and left limb, lasting seven weeks, and resembling, only in a much milder form, the pain which she has since suffered. The treatment was by leeches, wet cups, etc.

After this the catamenia became extremely painful, and dysmenorrhœa was constant for four years. At this time (four years ago) the dysmenorrhœa became more intense, and was accompanied by severe neuralgic pain, limited to the region of the left ovary. Patient remained in this condition until eighteen months ago, when there was a sudden increase in the severity of the attacks, probably due to frequent exposure to wet and cold. The catamenia ceased for three months, and corresponding to the menstrual periods there were attacks of intense ovarian pain, lasting about ten days. The treatment at this time was by leeches and ice locally, and the internal administration of morphine. After this time she was unable, on account of the severe pain in the region of the left ovary, to bear the weight of her body on the left limb, which was flexed and laid across the right as in *matus coxarius*.

Ovariectomy was performed, as her strength and health began to fail in consequence of repeated attacks of pain.

The left ovary was removed, and was of natural size, the stroma and capsule appearing normal on section. The relief afforded was complete, and she entirely recovered.

PARACENTESIS PERICARDII (*The Lancet*, December 19, 1874).—Mr. T. H. Bartlett reports the case of a young man suffering from acute rheumatism, in whom symptoms of pericarditis came on and rapidly increased in severity. The pulse and breathing were rapid and feeble, and the dyspnoea was urgent.

Cardiac dulness extended to one inch to the right of the sternum and to the upper border of the first rib above, though here the dulness was not complete. The limit of the dulness on the left side was uncertain, owing to effusion in the chest. On auscultation, the heart-sounds were very feeble and distant; no friction-sound. There was a faint mitral bruit. The character of the heart-sounds was not affected by posture. The impulse of the heart could not be felt otherwise than as an ill-defined movement of the chest-wall at the region of the apex, spreading over a space the size of a crown-piece.

It was decided to perform aspiration, and a No. 2 aspirator-needle was passed in the intercostal space between the fourth and fifth ribs, two inches to the left of the central line of the sternum. The needle was used as an exhausted needle; and as soon as the pericardium was penetrated, as shown by fluid freely passing into the aspirator, the point of the needle was pressed up against the chest-wall as closely as possible. The fluid flowed freely to fourteen ounces, and then stopped flowing. It was deeply tinged with blood, and deposited speedily a scanty coagulum, and subsequently a layer of blood-débris. The supernatant fluid, still somewhat tinged, had a specific gravity of 1024.

The patient showed immediate relief, and improved steadily until recovery was complete.

ANEURISM.—In his recent lectures on aneurism Mr. Holmes arrived at the following conclusions:

1. That rapidly-growing aneurisms with a thin or imperfect sac are best treated by immediate ligature, especially when caused by recent violence; and that the success of compression is doubtful in aneurisms growing towards the knee-joint, and in all others which advance rapidly.

2. That the Hunterian ligature has been about twice as successful in modern hospital practice in England as the results of the accepted statistics show it to have been.

3. That the results of the compression treatment in the same hospital have given as yet about the same average as those of the ligature, but that these results might be much improved by a more careful employment of the method.

4. That too long persistence in compression is to be deprecated, as being likely to interfere with the success of the ligature.

5. That flexion is often successful when used so as not to distress the patient, and is worthy of a trial in all cases in which it stops or materially checks the pulsation, but should not be too long persisted in when it is not at once beneficial.

6. That we have no evidence showing the utility of, or the need for, the less usual forms of treatment, such as galvanism, coagulating injections, manipulation, temporary ligature, or the introduction of foreign bodies. —*New York Medical Journal*, January, 1875.

ACIDULATED GARGLES IN TYPHOID FEVER.—M. A. Netter, alluding to the buccal element in typhoid fever, and to the beneficial influence of frequently-repeated acidulated gargles, draws the following conclusions:

1. Call the attention of the patients to the bad odor of their mouth, and inform them that not only in it, but also in the nose, there is something being secreted which poisons the whole system.

2. Place at their disposition an unlimited quantity of a solution containing two hundred grammes of decoction of barley, thirty grammes of honey, and twenty-five grammes of vinegar. Let them gargle and rinse the mouth with this frequently, and also snuff it into both nostrils. When they have commenced with this, it will be found so agreeable that large quantities will be consumed. —*New York Medical Journal*, January, 1875.

NOTES AND QUERIES.

SATURDAY, January 16, 1875.

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

MR. EDITOR,—As one of the "medical members" of the Board of Managers of the Episcopal Hospital alluded to in your complimentary notice, week before last, of certain supposed action of that Board in answer to an appeal from a majority of the Dispensary Staff, in relation to an alleged overcrowding of the "daily morning clinics," and to a proposed establishment of afternoon "special clinics," I beg leave to submit a few remarks which were written too late for this week's *Times*.

I wish to suggest, as an old contributor to the Hospital,—not as a Manager, since I do not speak for my associates,—that a general hospital which is still incomplete in its construction and insufficient in pecuniary resources, and in which the out-patient department is already thought to be disproportionately burdensome in cost, is hardly in condition to be used in hobby-riding, whether in the dispensary or wards. Least of all is it prepared for an expensive and difficult experiment in the department which is said to be already over-run and costing more than the Hospital can now afford.

Because a few enterprising young men, after not more than twelve months' trial of the service as it is, have come to the conclusion that the "general clinic" of the morning is too large for them to attend to properly, and now "therefore" propose to be converted into "specialists" to attend to selected cases in the afternoon, are the Managers to be driven by the fear of—well, anybody's "extraordinary" wonderment at their "Philadelphia prejudice," into sacrificing all other considerations to a hue and cry for "specialism"?

Supposing—what has not yet been "demonstrated," either by figures or by assertions—that the general clinics were so injuriously overcrowded, is there no better way to meet the emergency than to plunge into all the perplexities, inconveniences, increased expenditure, at least temporary confusion, and greater responsibility throughout, of an attempt to provide for and invite the attendance of additional crowds of special cases in the afternoon, in order simply to lessen the excessive crowd of miscellaneous cases in the morning? If the "special afternoon clinics" were to be "allowed," as you express it, think you that "Philadelphia

conservatism" should "allow" the perversion of the still restricted funds of the Hospital—hitherto intended for what, with a clear view of all that *out-patient specialism* can effect and pretend to, I do not hesitate to regard as a much higher and broader purpose—in an undertaking which could not be saved, by the best influences now within our reach, from proving much more pretentious than practically useful for years to come? A good deal of difference of opinion very naturally exists among the members of the dispensary staff as to the need and policy of this specialist arrangement. Although six out of eight agree as to the overcrowding, some protest against the whole idea of change, and others are unsettled, if not indifferent, as to the kind and form of remedy. There is nothing to show that any of these would be willing to give up his hold on any class of cases in the morning because another set of prescribers were expected to attend to such cases in the afternoon. It would be hardly fair to advertise that the doctors, each in turn, were to treat all the cases without discrimination before dinner, but that after dinner one was to claim superior skill with certain cases, and to monopolize their treatment to the exclusion of his colleagues. Nor would it be much more encouraging to the patients to be informed that they were to go to one doctor only, and avoid the others, and to choose the right one, too, if it was after dinner, but that before dinner they were not even to be allowed a Hobson's choice! In a word, if we must have "specialism," we must first catch the specialists. No stickler for specialism could agree to any harlequin arrangement which would make the generalissimo of the morning a specialissimo of the afternoon. In fact, Mr. Reformer, there are too many lions in the way!

I have just been reading some remarks of Mr. Erichsen in his recent admirable lectures on "Hospitalism," which seem so apropos that I have taken the trouble to copy them. They are in Lecture IV. ("On the Prevention of Hospitalism"), pp. 100 and 101 of the little book. He says,—

"Thirty years ago the out-patient department was insignificant in comparison to what it now is. Dispensaries then did the work that hospitals now undertake in this respect. Not only are there the usual general medical and surgical out-patients, but very commonly out-patient arrangements are made for those affected by a variety of special diseases. Not only has the augmentation in the number of out-patients become so great as to be a source of demoralization to the public at large, of loss and injustice to the great mass of medical practitioners, of wasteful expenditure and of serious embarrassment to hospitals, but the accumulation of these crowds of diseased, often of infectious people, in the entrance-halls and 'out-patient and casualty' rooms of hospitals, has become a source of serious unhealthiness to the inmates of these institutions."

Practical study of these matters, in different places during more than thirty years, enables me to agree fully with all of this from actual experience, and with a good deal more that might be quoted with advantage. There are many reasons why a large dispensary or out-patient service is not desirable in a general hospital, although a limited one is not easily avoided, and may be very useful. Still more objectionable is it, as Mr. Erichsen very clearly shows, when allowed to be conducted within the hospital building. The greater the size the greater the objection, as a matter of course. The Episcopal Hospital plan of construction includes a separate out-patient building, to be placed as far on the one side from the corresponding wing as the laundry and dead-house are on the other. The present arrangements are altogether temporary; and so ought to be the much more commodious and convenient rooms in the basement of the nearly completed second wing.

"Specialism," at least in the multiple and attenuated form now struggling into notice, was very little contemplated in our original hospital design. I suspect there will be ample time for its full consideration before the proper out-patient building is constructed. In the mean time, I trust the *Philadelphia Medical Times* may possess its soul in patience, and prevail upon its friends to wait more quietly. Some of them, perhaps, may be less dazzled in the lapse of years—say the "two or three generations" mentioned—with the view of the "special" pinnacles on which they are now so anxious to be perched.

We hear much about old-fogyism in all "progressive" movements. Is it not well to remember that *young-fogyism* is the rampant evil?—that it is at least as rife on these occasions, and much more apt to cost a great deal more in work and means than it comes to? Allow me just to hint, in conclusion, that although specialism is far from being a "new" thing in any sense among us, it still is, unhappily, a very crude thing in many places, and in many of its forms and aspects. If you wish to see some of these in their true light, please put on a clearer pair of spectacles. If the glasses must be colored, do let the tint be neutral. Above all things, don't let them magnify beyond ordinary comprehension when they are directed towards a mare's nest; and let the field of vision be large enough to take in a view of the question which may, at least, be worth a practical examination.

Respectfully,

EDWARD HARTSHORNE.

[WHEN we printed Dr. Knight's note last week, we supposed that he was correctly informed as to the matter concerning which he was writing, and accordingly acquiesced in his statement that we "had no case at all." Further inquiry has revealed the fact that we were right in our first position: the petition *did* come from the dispensary staff, one or more meetings of which were held about the matter, as stated in the notices issued, the staff being unanimous with a single exception. We therefore fall back in good order upon our original position. In regard to Dr. Hartshorne's letter, he greatly misunderstands us if he believed we had the slightest intent to "drive" him or the Board. We do not waste effort in attempting impossibilities. If he will re-read our editorial paragraph, he will see that it was written concerning *un fait accompli*, simply bringing it forward as an example of the opposition to specialism which certainly does prevail largely in the minds of the older members of the profession in this city. It is impossible to create skilful specialists without offering dispensary or hospital opportunities for them to perfect themselves. You will never get the loaf before you sow the wheat. To attempt to "catch specialists" before you have specialism is as foolish as to look for chickens where there have been no eggs. If specialism is "crude" among us, it is simply because the dispensaries and hospitals will not allow special departments in which specialists may be trained. If we have so much "rampant young-fogyism," certainly our crudeness is not because we are wanting in those of spirit and power to work out from this crudeness. We do not think this letter of Dr. Hartshorne's will convince any one that if he wanted special clinics there would be any insuperable difficulties in the way. If he really desired to go up to the palace called Beautiful, like Christian, he would find the "many lions" very harmless animals.—*Editor P. M. T.*]

TO THE EDITOR OF THE PHILADELPHIA MEDICAL TIMES:

DEAR SIR,—In the last issue of the *Times* your Japan correspondent portrays what he supposes to be an undescribed form of disease, which he designates "Japanese Leprosy." He states that he has never seen it "described in any medical work or journal," leading one to suppose that the symptoms are those of some new variety. The question of interest in the case is simply whether the leprosy of Japan is different from that of any other country. The symptoms detailed in the description of the cases cited are those of the well-known anæsthetic variety of the disease, as it is encountered in many portions of the globe, and certainly present nothing peculiar or new. If, however, there are other symptoms, not common to the leprosy of India and the East generally, which the leprosy of Japan offers, it will be of interest to have the same fully recorded, that our knowledge of this fearful malady may be thereby enriched.

Very respectfully yours,

L. A. DUHRING.

1416 SPRUCE STREET, January 19, 1875.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

A SPECIAL meeting of the Society will be held Monday, February 1, 1875, at 8 o'clock P.M., at the Hall of the College of Physicians.

Dr. Washington L. Atlee will deliver his retiring address as President. Subject: A Retrospect of the Struggles and Triumph of Ovariotomy in Philadelphia.

The medical profession in the city are cordially invited.

OFFICIAL LIST

OF CHANGES OF STATIONS AND DUTIES OF OFFICERS OF THE MEDICAL DEPARTMENT U.S. ARMY, FROM JANUARY 19, 1875, TO JANUARY 15, 1875, INCLUSIVE.

KNICKERBOCKER, B., ASSISTANT-SURGEON.—Temporarily assigned at Fort Vancouver, until the season will admit his joining his proper station.—Fort Colville, W. T. S. O. 5, Department of the Columbia, January 11, 1875.

KINSMAN, J. H., ASSISTANT-SURGEON.—Assigned to duty at Fort Seward, D. T., until further orders. S. O. 9, Department of Dakota, January 16, 1875.

HEIZMANN, C. L., ASSISTANT-SURGEON.—Granted leave of absence for six months, with permission to go beyond sea. S. O. 13, A.G.O., January 20, 1875.

WILSON, A. D., ASSISTANT-SURGEON.—Assigned to duty at Camp McDowell, Arizona Territory. S. O. 2, Department of Arizona, January 7, 1875.

SKINNER, J. O., ASSISTANT-SURGEON.—Leave of absence extended for one month, with permission to apply to the Headquarters of the Army for a further extension of three months. S. O. 7, Military Division of the Pacific, January 12, 1875.

SATURDAY, FEBRUARY 6, 1875.

ORIGINAL COMMUNICATIONS.

THE THERAPEUTICS OF FUNCTIONAL HEADACHE.

BY ALLAN McLANE HAMILTON, M.D.,

Lecturer upon Nervous Diseases at the Long Island College Hospital, etc.

ALL remedies for the alleviation of the several varieties of this condition may be included under the following heads:

- | | |
|-----------------|--|
| I. INTERNAL. | <div style="display: inline-block; vertical-align: middle;"> <div style="display: inline-block; vertical-align: middle;">Cerebral anæmiants.
stimulants.</div> <div style="display: inline-block; vertical-align: middle;">Those diminishing reflex irritation.
remote local congestion.</div> </div> <div style="display: inline-block; vertical-align: middle;">Cardiac sedatives.</div> |
| | <div style="display: inline-block; vertical-align: middle;"> <div style="display: inline-block; vertical-align: middle;">Alteratives.</div> <div style="display: inline-block; vertical-align: middle;"> <div style="display: inline-block; vertical-align: middle;">Malarial.
Syphilitic.
Gouty.
Rheumatic.</div> </div> </div> |
| II. LOCAL. | <div style="display: inline-block; vertical-align: middle;"> <div style="display: inline-block; vertical-align: middle;">Peripheral irritants.</div> <div style="display: inline-block; vertical-align: middle;">anæsthesiants.
revulsives.</div> </div> |
| III. GALVANISM. | |

The headaches dependent upon anæmia of the brain result usually from nervous exhaustion. These are the headaches of brain-workers, or may also follow unusual physical fatigue. The distressing persistency of the headache of nervous prostration is the characteristic feature. It is the most protean of all forms, as it may be a close counterfeit of neuralgia, or, on the other hand, may be dull and subacute. These patients are usually anæmic and much reduced. The headaches are associated with vertigo, and oftentimes nausea. There is usually vomiting, and sometimes syncope. The mental powers are exhausted, and the patient who suffers in this way usually awakes unrefreshed by sleep, with dull heavy pains and a sense of fatigue. There is little disposition to use the mind; the pulse is small and feeble, and there is sometimes a tendency to passive cerebral congestion. The skin is cool during the attack, and the surface may even be moist.

Many of my patients who suffer in this way are women, and the headache is the most distressing when the patients awaken. The use of a cup of tea or coffee is excellent at this time, and I have lately found that cocoa given in the form of a fluid extract is of very great benefit. Messrs. Hazard and Caswell have made for me a fluid extract which is quite concentrated. A drachm or two of this is the dose. The following prescription is a favorite of mine for these headaches:

℞ Strychniæ sulph., gr. i;
Acidi phosph. dil.,
Tr. ferri chlor., āā ℥vi;
Aquæ camphoræ, ad ℥iv.—M.

Sig.—A teaspoonful after eating.

The use of diffusible stimulants is in order. We may give the patient the aromatic spirits of ammonia and sherry wine several times a day with good results. Muriate of ammonia is an invaluable remedy in these headaches, particularly in hemicrania; it should be given in very large doses—from ten grains to thirty—every hour until relief is obtained.

A form of headache spoken of as *hyperæsthetic* by Hanfield Jones demands opposite treatment, for the administration of stimulants aggravates it greatly. These are the cases where there are redness of the face, tense carotids, injected conjunctivæ, and heat of skin. The patient is very restless, and the mental faculties are confused. These patients have cold hands and feet during the paroxysms, as a rule. There is imperfect nervous stimulation of the heart, and the cerebral vaso-motors are subject to paresis. These patients find it difficult to sleep; there is tossing at night, and the mind is possessed by a myriad of thoughts that chase each other through the brain. The first order of remedies in my table are of value here, and the bromides are the best of them. We may give this prescription and hope for good results, sometimes very immediate ones:

℞ Sodii bromidi, ℥i;
Fld. ext. ergotæ, ℥i ss;
Aquæ camphoræ, ad ℥iv.—M.

Sig.—A teaspoonful every three hours, or two teaspoonfuls at night.

I believe the sodic salt to be the most efficacious of all, and the most reliable. Bromide of calcium is next in order, I am convinced, after having given it an extended trial.

In these headaches cardiac sedatives are of incalculable benefit. Tincture of aconite and veratrum viride will often produce happy results. The continued use of digitalis, combined with zinc, the latter in the form of the oxide, does much to change the character of the circulation.

For the headaches of inebriety I have used since the year 1871 the monobromate of camphor. The results of my experiments I published in the *New York Medical Journal* of August of that year. I am sorry to see that this excellent remedy has fallen into disuse, for it seems to possess hypnotic properties peculiar to itself.

Bourneville, of Paris, has recently called attention to its physiological effects, and I trust its use will be more extended, it having received favor at the hands of this distinguished gentleman. Local depletion, and, in some cases, general depletion, are necessary. Leeches and cupping relieve the gorged sinuses at the base of the skull. A very common class of headaches are those dependent upon reflex causes. They may be called the *inhibitory* headaches. They go hand in hand with disturbance of digestion, irregularities in the uterine functions, and with other conditions dependent upon eccentric irritations transmitted to the central nervous axis. These headaches partake of all varieties: we may have the well-known sick-headache, the headache of dysmenorrhœa, or that associated with an irritable uterus. Of course, our diagnosis will point out the cause very quickly; but oftentimes there are points of irritation we may overlook. Hemorrhoids may often produce headache, associated with great restlessness and fatigue. Its seat is usually in the frontal region, and it comes on very suddenly.

The uterus will account for two-thirds of the headaches among women; and one of my patients now under treatment suffers with a common form

all have met with undoubtedly. Her uterus is retroverted: mechanical pressure is made upon the rectum to such a degree that the walls of that gut are in contact nearly all the time. A headache is the result, which is persistent and very prostrating. She suffers constantly from constipation, and before I saw her was often in such extremities from retained feces that she would pass an ivory paper-cutter up the rectum and press the uterus forward. After working in this manner for some time, and using a syringe, she would have an unsatisfactory, ribbon-like, and greatly attenuated stool, and the headache would disappear for several days. These cases are more familiar to the gynecologist than to the neurologist.

Just as the stomach, when irritated by undigested food, transmits to the brain in gastric epilepsy a morbid irritation, and a convulsion is the consequence, so does it send irritations, that are followed by headaches.

We are to meet these conditions therapeutically by special interference and proper remedies.

There is a somewhat rare variety of headache, but an excessively painful one,—I allude to rheumatic headache. The pain is superficial; there is a diffused hyperæsthesia over the scalp, which is very sensitive to touch. The disease may be deeper, and the dura mater be the seat of rheumatic inflammation. This is the rare variety. The external hyperæsthesia is due generally to cold. I have found it amenable in a very few minutes to the faradic current applied by the wire brush. Of course, alterative medicines will be required should there be much constitutional participation.

Headaches are associated with syphilis in nearly every instance. Oftentimes there are deep organic changes, sometimes of the dura mater, or there may exist a tumor. The headache is intense, localized, and not always attended by acceleration of pulse. It is needless to say it is worse at night. Inunctions of mercurial ointment have met my anticipations in many cases. In old cases we naturally resort to specific medicine.

The suboccipital headache of malaria is often uncontrolled by quinine alone. The combination of arsenious acid is of great use, and the addition of a small quantity of belladonna increases still more its effect.

Neuralgia is dependent upon so many causes that it will be difficult to consider its therapeutical indications without going very deeply into the history and etiology of the disease. The peripheral forms, however, deserve notice in a paper devoted to the discussion of functional diseases, and, as these are very commonly met with, particularly the facial form, it might be apropos to speak of a few serviceable remedies. I know of none so good as iron, quinine, and belladonna, or arsenic in some one of its forms. This prescription is a good one, I think, as it contains three of these agents:

R Morph. sulph., gr. vi;

Ext. belladonnæ,

Ext. nucis vomicæ, āā gr. xii;

Ferri et quinæ citrat., ℥iiss.—M.

Ft. massa et divid. in pil. No. xlviii, one t. i. d.

Strychnia is of great benefit in the anæmic variety of this disorder.

Peripheral neuralgia is treated most successfully by local applications, and among these come galvanism, chloroform, irritant applications, such as blisters, etc., and the actual cautery. The application of chloroform and of bisulphide of carbon has been recommended by several English writers. One of these substances should be poured upon a piece of cotton, and the same placed in a wide-mouthed bottle. The mouth of the bottle is to be then held against the most painful part of the face for a few minutes. A few drops of nitrite of amyl inhaled have often stopped a severe neuralgia.

The hypodermic syringe is so much used that it would be unnecessary to allude to it. I would only speak of certain solutions that have been tried with different degrees of success.

Morphine stands prominently forward as the best. Combined with atropine it is perhaps more efficacious than when injected alone. In neuralgia, chloroform injected hypodermically has been highly recommended by Roberts Bartholow. I think its greatest fault is the production of abscesses. I have used it several times, but have always had unpleasant consequences of this kind. The irritant nature of this drug forbids its application to the skin even locally. We have all seen the blistering, produced by the local application. How much more intense must be its action beneath the skin!

Blistering the skin, and afterwards applying morphine to the denuded surface, is effectual in stopping some forms of peripheral neuralgia.

I have lately tried, with the most satisfactory results, the local application of the ether-spray by the atomizer. Freezing of the skin just anteriorly to the ear will cut short a violent attack of facial neuralgia in a few moments.

In certain forms of facial neuralgia, particularly where there are points of irritation, the actual cautery-iron, brushed over these points, will cure the patient.

Perhaps one of our best remedies is electricity. In the form of galvanism we may affect the cervical sympathetic, diminish the cerebral hyperæmia, or by stronger currents increase it. The poles should be held over the nuchæ or lower down, and over the mastoid bone, or upon both temples. In neuralgia the positive pole may be held just back of the ear, and the negative passed over the several branches of the fifth nerve.

The faradic current often relieves many headaches, particularly if they are diffused over the scalp, and if they are aggravated by heat to the head, or by pressure.

The application of cold is one of the best local means we have to modify or stop headache, particularly if it be of the hyperæsthetic variety. Bladders filled with ice, cold douches, and other expedients enable us to successfully combat it.

The organic headaches deserve mention by themselves, so I will not venture upon such a wide field. In all cases of this kind it is a symptom, and, while attempting to relieve it, we must not forget that there is generally a cause.

CRITICISM ON A SO-CALLED CASE OF
"INFECTION BY SYPHILITIC SEMEN."

BY FRED. R. STURGIS, M.D.,

Lecturer on Venereal Diseases in the Medical Department of the University of the City of New York, etc.

IN the November number of the *New York Medical Journal* for 1874, a case is recorded by Isaac Smith, Jr., M.D., of Fall River, which is very curious, and, did it prove what it claims to, would be highly valuable. It is headed "Infection by Syphilitic Semen," in which the writer states that he believes he is possessed of facts which will in the future render the ultimatum untrue, that proof of infection by syphilitic semen has ever been adduced in a single instance.

That I may state the case candidly and honestly, I shall copy the doctor's case in full, and then give my own criticisms.

"In February, 1872, a gentleman called upon me for advice about a sore 'he had upon his penis.' Upon examination, I found behind the glans penis a circular excavation, with indurated and raised circumference, three-fourths of an inch in diameter; said he had had it six weeks; had been under the care of a doctor, who said it was only a 'chafe.' I placed him under mixed treatment and mild citrine ointment locally, and the chancre healed in about two weeks, leaving a cicatrix. In a few days he called and said he was 'breaking out,' and examination revealed the secondary eruption, which in a short time completely covered every part of the body. Treatment was not changed. Salt-water bathing was advised, and in a short time his skin was as fair as before infection. Next, engorgement of the glands both sides of the neck ensued, which was successfully treated by hypodermic injections of iodine, in conjunction with original medicine; one of the glands suppurated, but healed kindly after aspiration and subsequent injections of iodine; almost without cicatrix. The inguinal glands were prominent, but did not require specific treatment. A year passed on, and, disregarding my advice, he was married. I unfortunately assured him, however, that his wife would suffer no detriment *unless she became enceinte*.

"In August, 1873, his wife had prolapsus uteri, and he discovered a sore upon the os, which he attributed to friction. I treated the chancre (for such it was) and put her under mixed treatment,—*i.e.*, iod. potass. et hydr. chl. corros., etc.). This chancre healed in about the usual time, and, the uterus having been elevated, its natural position was retained there by a pessary. Six weeks later I was called to attend her for 'rheumatic fever,' as her husband called it. It was, apparently, in the incipient stage of that disease. The temperature was very high, and articular swelling was present at the larger and smaller joints. The urine was intensely acid. I thought proper to put her under the influence of alkaline treatment, omitting other remedies, which was continued until the urine was loaded with ammonia-magnesian phosphates, and alkaline in reaction, during which time perspiration was profuse, and as that subsided the secondary eruption

appeared. The mixed treatment was now resumed, and the case progressed favorably; the mucous membrane of the nose was slightly affected, but healed under the stimulus of dilute citrine ointment.

"January, 1874, the gentleman called to tell me he had caught disease from his wife. I found he had a urethral chancre, which I treated. As yet there are no secondary symptoms. I was called to his wife also two weeks later, and found her suffering fearfully from engorgement of the os uteri with uterine leucorrhœa, which was treated through the active stage with opiated emollient injections. The active symptoms subsiding, the discharge increased, and I used intra-uterine injections of dilute citrine ointment, which rapidly caused a cure. Since then she has been free from dysmenorrhœa, which she has suffered from since her first menstruation, at times having to remain in bed a week on account of its severity. She has had three painless menstruations since, and is apparently in perfect health.

"She *has never been pregnant*; has never run past her time."

To summarize: a man has a chancre, followed in a little over eight weeks by a secondary eruption and glandular engorgements. By the way, there is no history of mucous patches, one of the most common lesions in this country. A year after his primary lesion, he marries; and six months later—eighteen months after his primary lesion—he infects his wife. The question now is, How? Dr. Smith says, by the semen.

Before allowing this mode of contagion—a point yet *sub judice*, and opposed by many good authorities and by clinical experience—let us see if Dr. Smith has eliminated all other sources of infection, not those remotely possible, but those most probable. And here we are met at once by disappointment. Not one word about the man's subsequent condition from the time he was under the doctor's care until the time of his wife's infection; not one word about his condition or about any manifestations of his disease at or just prior to the time he poisoned his wife. Of course, the man must have been syphilitic, or he could not have conveyed syphilis to his wife; the disease must have been latent in him. Are urethral mucous patches so extremely rare as to be entirely excluded as a probable means of contagion? Which, in the present state of our knowledge, is considered most unusual, the existence of mucous patches in the urethra or direct infection by the semen? Until the existence of this lesion in the canal, upon the membrum virile, or upon any other part of the body capable of affording a means of contagion, be excluded, we are forced to render a verdict of *non-proven*.

The *probable* seat of the lesion is pretty well narrowed down by the presence of the chancre on the os uteri of the wife. Had this not been explicitly stated, it might have been a question whether the disease was not conveyed by kissing, as mucous patches of the mouth are as dangerous as are the primary lesions.

But perhaps it may be asked, Why suspect the presence of mucous patches? For three reasons:

first, because they are the most common lesion of the earlier manifestations in syphilis; second, because they are often overlooked or misunderstood when seated upon the mucous membrane of the penis or in the urethra; and third, because it is more than probable that the man had one within six months after infecting his wife. This Dr. Smith seems to have regarded as a fresh infection, for he speaks of it as a "urethral chancre," adding, "as yet there are no secondary symptoms."

Thus we have a man still under the diathesis of syphilis (for he infected his wife only five months previously) become re-infected, for I suppose the chancre was a primary lesion, and, *mirabile dictu*, going from January to the following November, when the case was reported, without any signs of subsequent symptoms. Now for this chancre; was it a chancre, a chancroid, or a mucous patch?

Chancre, *i.e.*, primary lesion, it can hardly have been, unless our doctrines on syphilitic re-infection are totally untrustworthy: *a man while intoxicated by syphilis does not recontract a primary lesion*. It is to be regretted that the character of the ulcer is not described, and that the condition of the inguinal glands is entirely passed over.

Chancroid it could hardly have been, as the patient "caught disease from his wife," and in her there is no history of chancroid.

Mucous patch? impossible to assert it was, as no description is given of the ulcer. The probabilities are more in favor of this than any of the others.

It would be interesting to have the subsequent history, symptoms, etc., of both, and it is to be hoped that Dr. Smith will give them. The reason I have so freely criticised this case is that it lacks everything to make it convincing, and when the attempt is made to prove so difficult a point as this every possible source of error should be carefully eliminated. I think I may therefore be excused the part I have played in tearing it to pieces; the theory of the transmission of syphilis by the semen rests upon other cases no better than this, and it is only by pointing out their weak spots and guarding in future reports against them that we can ever hope correctly to solve the problem.

At any rate, Dr. Smith must waive his claim of having proved any such hypothesis as heads his paper, and rest content "with the duty of recorder."

16 WEST THIRTY-SECOND STREET, NEW YORK.

LOCALIZED REST IN THE TREATMENT OF PULMONARY AFFECTIONS.

Read before the Philadelphia County Medical Society, November 25, 1874.

BY HORACE Y. EVANS, M.D.

FROM time out of mind there has been a persistent crusade against the corset, yet neither the denunciations of the doctor nor the warnings of the parents could control the sway of the goddess of fashion.

Thrice have queens during their pregnancies endeavored to discard the stay, but so infatuated had

their followers become with it, that even the wielders of the mighty sceptre could not arrest its charms. This practice of compelling the abdominal organs to impinge upon those of the thorax and pelvis, we all know, brings with it a train of positive ills, yet from this evil practice of the ladies we, as physicians, can receive suggestions of practical importance in treating other diseases.

It has no doubt been observed by many of us that, as a rule, pleuritis in women is of shorter duration and of a milder character than in the opposite sex. It has occurred again and again in our experience to have lady patients suffering with an attack of pleurisy put on their stays, get out of bed, and go about their household duties not only with comfort but with positive relief. The priority of application of this stay-principle in the treatment of pulmonary affections appears to rest between Drs. Berkart and McCrea.

The former, in an article in the London *Lancet* of October, 1873, entitled "Rest in the Treatment of Consumption of the Lungs," suggests this principle, and enforces its applicability, not only by most apropos comparisons and illustrations of the successful employment of rest in diseases of other organs, but also by his successful use of it in the treatment of pulmonary phthisis. To Dr. McCrea,* of Belfast, however, we are indebted for a more minute description of the means employed, and a more extended application of the principle.

Of its usefulness he says, "I have seen no remedy equal to strapping the chest in efficiency and general applicability." His experience in its employment had extended over a period of two years, and in almost every variety of chest-diseases.

Dr. F. T. Roberts† says that it is very valuable in certain cases; it relieves symptoms, arrests cough, and thus prevents hæmoptysis.

The mode and means now generally employed to control motion in the thoracic walls is almost identical with that first suggested by Drs. Berkart and McCrea, though the latter, in a recent number of the London *Lancet*, states that he now uses the emplastrum roborans (emplastrum ferri, U.S.) instead of the emplastrum resinæ.

In our hands, the latter, when fresh and thickly spread, was as satisfactory as could be expected of any temporary application of like character. There are two sets of strips employed,—vertical and horizontal. The length and width of the vertical one will depend upon the size of the individual to whom the application is to be made. As a rule, however, it should be three and a half inches wide, and of sufficient length to reach from the sixth rib anteriorly to a corresponding point posteriorly. The horizontal strips extend from the sternum to the vertebræ, and vary from three-fourths to two inches in width.

The vertical strip should be put on first, fastening it firmly in front, and at the moment of deep expiration pulling it over the shoulders and fixing it on the back.

* Dublin Journal of Medical Science, Nov. 1873, and *Lancet* of July 18, 1874.

† London Practitioner, August, 1874.

The horizontal ones are next applied, from apex to base of chest-walls. The ends of the horizontal strips should be covered by broad pieces of plaster to prevent their loosening. The patient should be directed to endeavor to limit the depth of his respirations until the straps are firmly set. The whole or part of the chest thus covered may then be coated with starch or collodion. These are but general directions, which must be modified as circumstances demand. We very soon discovered that the ribs could be compressed to better advantage by lengthening the vertical strip anteriorly as low as the umbilicus.

In applying the horizontal ones, it will be found that in many instances the skin and its subinteguments will wrinkle, and thus leave a large portion of the surface untouched by the plasters, and, as a consequence, lessen their stability. This can be partially overcome by placing a compress of linen two inches wide and one inch thick against the side, from the axilla downward. The skin will fold or wrinkle against the edges of the compress, and yet give a central point of fixedness for the strips.

In our hands this apparatus required renewal once a week.

In cases where pulmonary abscesses are in process of evacuation, and the chest-walls becoming depressed, great comfort will be afforded the patient by placing compresses over such depressions before applying the straps; in addition to the comfort given, this seems to assist in evacuating the vomicae and facilitate cicatrization.

Our experience in this mode of treating chest-affections is limited to thirteen cases: six of tubercular phthisis (four chronic and two acute), two of pleurisy, four of pneumonia, and one of emphysema.

All the subjects were adults. As we are not an enthusiast in the matter, the simple result as noted will be briefly related.

In the acute stages of tubercular phthisis, pneumonia, and pleurisy, the pain was unquestionably modified, and the cough arrested to a greater extent and with less objectionable sequelæ than by internal medication.

In none of the phthisis-cases was there an attack of hæmoptysis during this treatment.

In pleurisy, the number of the respirations was reduced four to six per minute by the application of the straps.

In the large majority of the cases the patient at once expresses feelings of comfort following the dressing.

In pleurisy *alone* can we give this mode of treatment a higher title than a reliever of symptoms. In the two cases to which we have referred, the duration and severity of the disease were both modified.

Its success in this condition will be at once manifest when we remember that the beneficial effects are attributed to the relative immobility of the pulmonary parietes; if then, by this means, as we have just shown, we can control the extent of the motion of the costal pleura and at the same time

lessen the number of respirations, an active irritant to the inflamed surface is removed, and they can all the sooner be restored to a healthy condition.

As we have stated, we believe the principle of localized rest in chest-affections to be a correct one, but we have not as yet reached that perfection in appliances to the chest that the surgeon has in controlling motion in fractured bones and inflamed joints.

EXAMINATION OF HEIDENBLUT'S STOMACH AND ITS CONTENTS.

BY CARL SEILER, M.D.

THROUGH the kindness of Dr. W. W. Keen, whom I had the pleasure to assist in some experiments on the body of Heidenblut (executed on January 20), I came into the possession of the stomach and its contents, which I wanted to examine as to post-mortem digestion, and as to the nature of the acid in the gastric juice.

The organ was removed from the abdominal cavity exactly two hours after death; the last meal, consisting of two boiled eggs, bread and butter, and a cup of coffee, having been taken three hours before the execution. I took the stomach to the University of Pennsylvania, and there emptied it, and opened it in the presence of Prof. F. G. Smith.

The contents were a semi-fluid, with a few pieces of undigested egg and bread floating in it. The mucous surface of the organ at the greater curvature near the pylorus was very highly injected, and presented a deep red color, while the rest of the mucous membrane was much paler, and appeared perfectly healthy. This dark hue was well defined, so that it could easily be recognized, even at a distance.

This condition of things was ascribed to post-mortem digestion, and Prof. Smith exhibited it as such to the class, the color having, however, somewhat changed after the opening of the organ by the unavoidable exposure to the atmosphere. The contents were divided, Prof. S. keeping one part, and I taking the other for chemical and microscopical analysis.

The microscope proved that the darker portion of the mucous membrane had undergone partial digestion, as the villi were seen to be sloughed away, while they appeared perfectly natural in the paler parts of the membrane. Dr. T. G. Hunt kindly examined the specimens and corroborated my observations.

The contents exhibited the usual appearance under the microscope, containing epithelial cells, mucus, oil-globules, starch-granules broken and whole, and undigested pieces of bread and white of egg.

The chemical experiments were made, with the kind assistance of my friend Mr. F. H. Rosengarten, in the following order:

1. After apparatus and materials were proved chemically clean and pure, and after an acid reaction of the mass to be analyzed was proved by test-paper, we added some nitrate of silver to a portion of the mass, which gave a dense, thick precipitate

of chloride of silver, proving the presence of chlorides.

2. A portion was placed in a distilling-vessel and gently heated on a sand-bath. The vapors and distillate gave an acid reaction, but no precipitate was formed by the addition of nitrate of silver, except a faint opalescence, probably due to some organic matter. This proved that no hydrochloric acid was present, for this acid would have distilled over at the temperature obtained, and been detected by the silver salt.

3. A portion of the material was neutralized with caustic soda, and heated in a test-tube. To this was added a hot solution of proto-nitrate of mercury, which gave a muddy precipitate, which, after standing for some time, settled and left the supernatant liquid clear, and of a dark-red color. In it, after evaporation, the rosette-shaped crystals of lactate of quicksilver showed themselves under the microscope; the salt produced being $\text{Hg}_2\text{O}, \text{C}_6\text{H}_5\text{O}_5 + 2\text{HO}^*$

4. To another portion of the material, freshly-made carbonate of silver was added, and the mixture boiled and filtered. In this filtrate the peculiar brush-shaped crystals of lactate of silver were found, and produced a beautiful effect of color under the action of polarized light. $\text{AgO}, \text{C}_6\text{H}_5\text{O}_5 + 2\text{HO}^\dagger$

5. Neutralizing with baryta-water gave no evidence of the presence of sulphuric acid; the addition of sulphate of zinc to the baryta solution produced a precipitate of sulphate of baryta.

6. This was filtered, and the liquid found to contain the characteristic crystals of lactate of zinc. $\text{ZnO}, \text{C}_6\text{H}_5\text{O}_5 + 3\text{HO}^\ddagger$ Other lactates were produced, and their crystals recognized under the microscope.

These results of our experiments, I think, go to prove that the acid reaction of the material was due to lactic acid and not to hydrochloric acid. The tests for sugar were also applied, and glucose was found, thus showing the conversion of starch into this material in the interior of the stomach and perhaps during the act of mastication and insalivation.

PHYSIOLOGICAL LABORATORY OF THE UNIV. OF PENNA.

NOTES OF HOSPITAL PRACTICE.

PENNSYLVANIA HOSPITAL.

SERVICE OF R. J. LEVIS, M.D.

Reported by Dr. JOHN B. ROBERTS.

GUNSHOT WOUND OF THE LEFT LUNG PRODUCING LARGE PLEURAL EFFUSION—PARACENTESIS THORACIS BY THE ASPIRATOR, FOLLOWED BY FREE INCISION OF THE CHEST-WALL—CONVALESCENCE OF THE PATIENT.

GEORGE E., aged 19, was shot by a policeman who fired at him as he was endeavoring to escape, the bullets taking effect in the back. The first entered one inch to the left of the sixth dorsal spine, passing upwards and somewhat inwards, while the other struck about four inches to the left of the seventh vertebral spinous process near the angle of the scapula. The wounds

showed that the bullets were large, and it was evident that they had penetrated the lung, from the profuse hemorrhage that occurred by the mouth; evidently proceeding from some large bronchial vessel injured by the bullets which entered near the root of the lung where the great vessels are situated.

When admitted to the hospital, the patient's face was blanched, he presented the symptoms of shock and exhaustion from hemorrhage, and while in the receiving-ward expectorated a large amount of blood. In order to induce reaction, morphia, in conjunction with stimulants, milk, and beef-tea, was administered.

On examination, eight hours afterwards, the existence of pneumothorax on the left side was diagnosed from the marked tympany present, and the displacement of the heart, which struck the thoracic wall on the right side of the sternum. Loud râles were heard over both lungs, the expectoration of small amounts of blood continued, the pulse was 130, and the respiration 38 per minute. As the patient had reacted by this time, the administration of stimulants was discontinued, and one drachm of infusion of digitalis ordered every fourth hour.

On the day subsequent to his admission, the patient complained of much distress in the left side, and began to show febrile symptoms, which were combated by the more frequent administration of digitalis, given with spiritus etheris nitrosi and liq. ammonii acetatis. Under this treatment the temperature fell from 102° to $98\frac{3}{4}^\circ$, and the pulse was reduced from 128 to 99, and became stronger.

This treatment was persisted in until the seventh day, when the boy sweat a great deal, and presented a red spot upon the cheek; he had, however, no chill. The digitalis was now considered unnecessary, and iron with quinine substituted.

By physical exploration it was found that there was a large effusion in the left pleural sac, which pushed the heart far to the right, caused great dyspnea, and produced, by its pressure upon the diaphragm, a troublesome hiccough, which was especially frequent after he took food into his stomach.

In order to relieve these urgent symptoms, for the patient was almost moribund, it was determined to tap the chest; and accordingly paracentesis thoracis was performed by passing the aspirating needle into the pleural cavity at the sixth intercostal space, about two and a half inches to the left of the nipple. Care was taken to keep close to the upper edge of the rib, lest, if thrust into the chest too near the border of the rib above, the point of the needle might strike the intercostal artery running in the groove at the lower edge of the rib.

After the abstraction of forty-eight fluidounces of dark bloody serum, great relief was given to the patient, and his respirations decreased from sixty to forty per minute. The puncture was covered with adhesive plaster, and the daily administration of stimulants ordered.

The boy continued in a very comfortable condition for five days, when he again became apparently moribund, having severe pain in the left axilla, an erysipelatous blush around the puncture made by the needle, and great oppression of breathing from the fluid which had again accumulated.

It was proposed to reopen the wound made by the aspirating trocar, in order to let the fluid drain off, but, as the orifice had closed, another puncture was made by a bistoury immediately below, in the seventh interspace, from which thirty-eight ounces of sanguinolent serum escaped. This second operation was followed by a manifest improvement in the patient's condition. His pulse, which previously had been weak and fluttering, became stronger and more regular, and there was much less difficulty in respiration.

After a time he once more became greatly prostrated,

* Liebig's Handwörterbuch, vol. v. p. 292.

† Loc. cit., 293.

‡ Loc. cit.

having a scarcely perceptible pulse, and it was thought that he was at last to succumb, but he again rallied and began to improve.

The wound is now kept patulous with a soft rubber catheter, to allow the fluid, which has become purulent, to drain away, and thus to remove as far as possible the danger of septic influences from the pus in the pleural sac. Still further to guard against the injurious effects of the purulent effusion, the cavity has been washed out daily with carbolic acid and water (3i ad Oi), about a gallon of which is forced through the opening and allowed to flow out by turning the patient upon his side. Instead of using a syringe for this purpose, the resident surgeon employs hydrostatic pressure as in Thudichum's nasal douche, which gives a continuous stream that can be kept up as long as necessary without disturbing the apparatus. The end of the tube which conveys the solution into the cavity is thrust in about four inches, and touches the pericardium, for the impulse of the heart can be distinctly seen moving it.

This method of treatment has been steadily continued, and now the patient presents no bad symptoms, but is convalescent. He was undoubtedly saved by tapping the chest, and thus removing the fluid pressing upon the lung; and has since been sustained by the administration of tonics and by the thorough cleansing of the pleural cavity with carbolized water.

The bullets, or at least one of them, are imbedded in the pulmonary tissue, and may hereafter occasion trouble; but at present his progress towards recovery is exceedingly satisfactory.

Now, about three and a half months since the receipt of the injury, the patient is walking about the wards.

BELLEVUE HOSPITAL.

SERVICE OF PROF. L. A. SAYRE.

Reported by WILLIAM A. GEORGE, M.D.

HIP-JOINT DISEASE.

CASE I.—The first case I wish to show you to-day, gentlemen, is that of a little child four years old, who has had hip-joint disease since last April a year, and who has been treated with one of "Sayre's" splints. Unfortunately, notwithstanding that, the disease has gone on to the third stage, and there is now an immense abscess formed on the outer side of the joint, which must be opened, and, perhaps, after opening and exploring the cavity we shall find the bone has become involved, and may require exsection; but even if we find this to be necessary, we shall not attempt exsection to-day, as the abscess is so large that it is better to allow its walls to contract before the operation of exsection is performed. As I told you, she has been treated with this splint for the purpose of extension and counter-extension, but, not being properly applied, the object for which the splint was constructed—extension and counter-extension—was not accomplished; it was applied by another person wrong side up, and did not exert that extension and counter-extension which Sayre's splint will afford when correctly put on. The reason I have brought this patient here to-day is to show you the dangers of not applying the splint exactly right, and in this boy, by way of contrast, I show you another case where the splint was properly used, and where the result, as you perceive, is a perfect cure. [Showing case recovered.]

The instrument on this child, in the first place, was not properly constructed. The instrument-makers generally want to improve upon the splint with some new-fangled notion of their own, which ends, in many instances, in rendering it useless for the purpose desired. You will notice, with the instrument upon her now,

which I have to-day placed there, the child is perfectly comfortable, notwithstanding this enormous abscess, and if you will watch her face when I make pressure on the limb, you will observe there is no pain.

I regret that I had not the opportunity of seeing this case before it became so bad. I shall not aspirate this abscess, but *incise*. Aspiration is a very nice little operation for draining off water from the bladder or serous effusions from the pleura or the joints, but in cases of cavities containing pus it will not do. [The Professor here opened the abscess.] You see with what force that gushed out. Now, having opened it freely, I explore the parts with my finger, and discover a firm band surrounding the joint like a capsule, which must be divided that I may make further examination; and here I find a small hole leading into dead bone. This abscess should have been opened months ago. I have now reached bottom, and find the sinus extends clear round the thigh, and therefore make this counter-opening, and draw the seton through. I now fill the wound with oakum soaked in Peruvian balsam; I then cover the outer part of the limb with a large wad of the same material, securing it there with a roller round the limb, which roller also serves the purpose of contracting the walls of this extensive abscess, and with this dressing the pus will continue to discharge, just the same as if there were no obstruction. This, gentlemen, is the peculiar advantage of oakum as a dressing in all cases of extensive suppuration. It allows the free percolation of pus through it, whereas lint, particularly cotton lint, acts as a tampon, preventing the discharge, and it is the retention of these noxious secretions which is the greatest detriment to the patient. Take a bale of cotton, put it in the East River; at the end of a year, when you take it out, the centre of the bale is as dry as when you cast it in, it being impermeable to fluids; hence the serious objection to the use of cotton lint to suppurating sores, and the immense advantage of this oakum dressing in all cases of extensive suppuration. I next put a piece of oil-silk over it, for the purpose of keeping the child's clothes from being soiled; we re-adjust the instrument, which was taken off for convenience in dressing, the mother in the mean time having kept the leg extended; she was the instrument while the instrument was off. Here in this bowl we have at least eight ounces of pus, in addition to what was lost at the first gush. I found an opening there leading into the joint, but there is very little destruction of the head of the femur, it being quite large, almost its normal size, only a small necrosed portion being found on its posterior surface, and as this opening is at the posterior inferior point of the acetabulum it may get well without exsection. The abscess is now open; there is no doubt about that [Laughter]; and if there is only a small portion of the bone involved it may perhaps be exfoliated without much further trouble.

A case very similar to this I saw some years ago in consultation with Dr. Jordan, in which the abscess was opened, and the finger passed into it discovered an opening in the capsular ligament, and carious bone was detected; but the extent of the abscess was so great—like the present—that exsection was not performed, but left for future operation after the walls of the abscess had contracted. A tent of oakum was placed in the opening, giving free exit to the secretions of the joint; and by firm compression around the joint with proper bandages, and the correct application of an extending apparatus, the child in the course of a few months entirely recovered, with quite a considerable degree of motion at the hip-joint. The abscess entirely closed, the child enjoyed perfect health, suffered no pain in the absence of instrumental support, and remained in this condition for nearly three years, but finally died of an acute attack of another disease. At the post-mortem, Dr. Jordan fortunately obtained the hip-joint, which I

have in my possession. Upon opening its capsule the joint appeared to be perfectly healthy, although the head of the femur was very abnormally shaped, the ligamentum teres being entirely destroyed, and the fossa, where it is attached to the head of the femur, covered by a fibro-cartilaginous membrane, which was continued over the irregular flattened head of the femur, being rather thicker than the normal articular cartilage. The joint in all other respects appeared perfectly healthy, although the head of the femur had been thus irregularly shaped by the carious exfoliation during the previous existence of the disease, showing that even cases of caries of the joint with open sinuses sometimes recover with a moderate degree of motion. The ordinary rule with a joint thus open with carious bone in it is further and further destruction, and therefore exsection is necessary; but in some very rare instances, as in the one just quoted, free exit to the secretions being obtained, reparative inflammation may take place instead of destructive inflammation, and sometimes result in recovery without exsection. We shall therefore give the child the opportunity of being restored without an operation, if possible, and proceed to exsect it at some future time, if necessity requires.

Case II.—In this young man, gentlemen, I present to you a case of hip-joint disease [previously referred to] which, I think, is cured,—we will see to that presently,—and will serve to illustrate the correctness of several points in the treatment to which objections have been made. Dr. Yale will read to you the history, from the case-book. “Willis W., æt. 12; saw him for the first time April 1, 1872. He says he has been lame off and on for more than a year; has been supposed to have rheumatism, and received treatment for that complaint. Getting no better, he is brought here. *Present condition.*—Pain principally in the right knee, and has been so for the past six months; right limb abducted, flexed, and fixed; experiences great pain on pressure or adduction. *Diagnosis.*—Hip-disease, right side, second stage. *Treatment.*—Extension by weight and pulley, and short splint.

“April 10, 1872.—Applied short splint.

“October 9, 1872.—Has been dressed once by Dr. Yale since above date; to-day find the child much improved; re-adjusted splint.” Here, gentlemen, has been an interval of six months with only one dressing, and yet Dr. Taylor says, and prints it, too, that this splint cannot be applied so as to remain in position without being changed every few days.

“February 9, 1873.—Four months since last seen. Re-adjusted dressings at lecture-room, Bellevue Medical College; *very much improved.*

“May 17, 1873.—*Greatly improved; re-adjusted dressings.*

“December 26, 1873.—Splint re-applied; *very much improved; motions almost perfect; flexings somewhat limited; carefully examined by Dr. Sayre.*

“June 10, 1874.—Splint re-adjusted; *improving rapidly.*

“November 18, 1874 (that is, to-day).—*Entirely well, with almost complete motion, flexion being the only defect, and this only slightly less than normal. I remove all dressings, the plasters being in the same place as when applied, June 10, and discharge him cured.*”

I have dressed his leg six times since April 10, 1872, or, on an average, once every four or five months. Two years ago, when the splint was first applied, this limb, on account of the effusion in the joint, was flexed, fixed, and abducted. To-day I remove the plaster from his leg, as you see, and along with it the entire external cutis of his thigh, from one end to the other, comes off, the plaster having retained its position exactly where I put it at the last application. You have now seen this

disease in the number of cases presented to you during the last few weeks in all its stages, and here in this case the cure complete.

Case III.—I will now show you another one, in a little child who was brought to me a few days ago, and who had, as was stated, been using a Sayre's splint, but for my part I cannot imagine how a man could make such a mistake. It resembles, to a great extent, Dr. Hamilton's hip-joint splint for the purpose of keeping the joint quiet, and when you wish to fix a joint and render it absolutely rigid, this wire-gauze splint is a very useful instrument for the purpose, but in the treatment of hip-joint disease I do not want to keep the joint at rest. If the disease belong to the capsular and ligamentous portions of the joint, those parts must be kept at rest, but in hip-joint disease the bones, articular cartilages, and synovial membrane are the parts involved, and the capsular ligament has nothing to do with it; besides, if these ligamentous tissues are kept quiescent for any length of time, they undergo pathological changes, losing their elastic property, and consequently the ligaments and muscles require movement, but the bones of the joint require to be relieved from pressure, and the capsular and other ligaments which are not involved in the disease should be moved in order to retain their normal condition. Perfect and entire rest of healthy joints will end in complete ankylosis. You may cure with this splint,—with ankylosis,—and if this is the best that can be done, in Heaven's name do it; but if you can obtain *motion* in addition, then all the better. This surgeon, having secured rigidity of the parts, modified the splint of Dr. Hamilton by placing a firm piece of sole-leather on the inner side of the knee secured to the outer portion of the gauze splint by a band, and, buckling that tight around the femur above its condyles, presumed that he had so modified the instrument as to be justified in calling it a Sayre's splint, and thought that it would answer the very same purpose, forgetting in the mean time to apply the ratchet and key, by the use of which a graded extension could be applied to the limb, which is the essential principle in my instrument.

Now for the treatment. He wants extension at about that angle (the heel a foot higher than the table, the patient lying down). First apply a strip of adhesive plaster on either side of the leg, extending above the knee some two inches, to prevent traction on the lateral ligaments of the knee-joint; secure with a carefully-adjusted roller, taking care to over-lap the plaster and to take an extra turn around it with the roller, leaving the lower ends of the plaster projecting at the malleoli for night extension by means of weight and pulley. Next apply a many-tailed fan-shaped adhesive plaster on the outer and inner sides of the thigh, measuring first with your extension-instrument, so that the tags of the plaster will exactly conform to the places of attachment upon it. Having secured these with a roller, using care at the upper part of the thigh to reverse first each alternate tail of the fan-shaped plaster in carrying round the roller, and with another turn taking in the others,—braiding them in-and-in, basket-fashion,—run the roller down to the knee, and sew. Now apply the extension-instrument, which consists, as you see, of a circular cross-bar surrounding the crest of the ilium, well padded on its inner surface, and at its two extremities a perineal band for counter-extension; on its outer surface a ball-and-socket joint, from which runs an iron rod or bar down the outer side of the thigh to within two inches of the lower extremity of the femur. This outer bar is divided into two sections, one running within the other, and gauged or controlled by a ratchet and key which can make it longer or shorter. At the lower extremity of this outer bar is a projecting branch going around to the inner surface of the thigh, to receive the attachment from the plaster on its inner surface. Both of the

lower extremities of the instrument terminate, as you observe, in a roller or wheel, over which the tags are attached to the two buckles placed at the lower extremities of the instrument, as per cut annexed. In apply-

DR. L. SAYRE'S HIP-SPLINT.

ing it, first buckle on the straps at the lower extremity of the femur, then pass the strap under the femur to the buckle at the outer side of the instrument for the purpose of keeping it in place. We now pass the perineal band from one end of the upper part of the cross-bar around the perineum, and buckle it with sufficient tightness to be comfortable; next we insert the key into the ratchet, and make gradual extension until the patient is made perfectly easy, and until compression can be made upon the femur against the acetabulum without causing pain. The object of this key and ratchet is to obtain accuracy of adjustment, which is much easier effected than by buckling and unbuckling the straps, which would have to be done very frequently to accomplish the same purpose. The extension can be applied with so much force as to do great damage by obstructing the circulation in the perineum, and many think that the extension is to be applied for the purpose of drawing the head of the femur out from the acetabulum, which is an impossibility. The object of the extension and counter-extension is simply to prevent concussion of the head of the bone against the acetabulum, and for this reason it is always necessary to make your perineal band of a non-elastic substance; yet many persons in using this instrument have made the perineal band elastic, which may answer the purpose of giving ease to the patient under ordinary movements, but if any additional weight is placed upon the limb, the elastic perineal band, giving way under pressure, would necessarily fail to protect the bones from coming in contact. You will therefore see the necessity of the non-elastic perineal band; and the key, which, you will observe, regulates the elongation and shortening of the instrument, can be so manipulated as to give the nicest accuracy of adjustment, and, consequently, the greatest ease and comfort to the patient. You will now perceive, when it is applied and the extension properly adjusted, that I compress the femur over the knee with sufficient force to move the entire body without giving him the slightest pain. We will now reverse the key to take off the tension, and you will observe the lightest pressure upon the knee causes the patient to wince in the greatest agony, and yet, as you see, by extending it with a few turns of the key I now make pressure, and you behold the face of the patient wreathed in smiles, exhibiting no traces of pain whatever. This dressing will remain for an indefinite period, and if any of you put on the plasters in this manner, they will stay on for any reasonable length of time, and not, as Dr. Taylor says, for only a few days.

Case IV.—The next I have, gentlemen, is one sent from a long distance for the purpose of having the knee-joint excised. It is one in which there has already been an exsection of the elbow-joint, with a good result, giving the patient perfect use of the joint. The girl is about fourteen years of age, and some two years since, while her elbow was yet sore, she had a fall,

and, in endeavoring to protect it, she received an injury on the knee. Extensive suppuration followed, numerous openings occurred, and the discharge was very abundant and continual. These openings which you see lead into canals connecting with one another, and pass in every direction around the joint. I will, however, since the patient is under the influence of an anæsthetic, perform the operation, not of exsection of the knee-joint, which is not involved in the disease, but of laying the sinuses open first, and talk to you about it afterwards. [The Professor here performed the operation, remarking the while the extent of the false membrane lining the various pouches and canals formed by the disease, its glistening appearance, the thickness of the walls, and the extent of the incisions which were required. Applying to the wounds Peruvian balsam, filling them with oakum, and passing over all a snugly-fitting and well-adjusted roller, he proceeded.]

This case is one of bursitis. It is not synovitis, scrofulous ulceration, or white swelling of the knee-joint; the bones have not been touched; the disease has been wholly around the joint,—extra-capsular in every respect,—and it is one of such importance, especially regarding its correct diagnosis, that I will call your attention to it a few moments longer.

As I before told you, two years ago this girl received a fall and consequent injury of bursa immediately over the patella. From that time to the present she has been laid up, and under constant treatment; abscesses formed, which at first were aspirated; no benefit having been derived from this, however, they were punctured; they formed again and again, made openings of themselves, until now, as you saw, all the parts around the joint were completely riddled with sinuses, which were connected with each other, as was demonstrated before the operation by using the flexible probe. The only way in which to treat such cases is to lay open the canals freely, when you can very readily tear away their lining membrane, which has been productive of the discharge, and which, being destroyed, may be replaced by healthy granulations.

The incisions, you observed, I made with great freedom up and down the leg, and this can always be done longitudinally parallel with the vessels and muscles with the greatest safety; but care should be taken in making them *around* the limb, as arteries and veins are severed and muscles divided by transverse incisions of only half the extent of these I have made up and down the limb. Those of you who have lived in the West or near forests are aware how quickly a tree dies when girdled, and you also know when the old farmer, going his rounds, discovers one of his cherry-trees "hide-bound," and, taking out his jack-knife, slits it from the crotch to the ground, he produces a beneficial, and not injurious, effect. Just so it is in cases like this before you.

But your operation is not complete with only these incisions. That lining membrane will still continue secretory action, which will last as long as does the patient. It must be destroyed; adhesive inflammation must be set up within its walls, and the parts for a time kept quiet, being careful, however, to prevent anchylosis by using passive motion at the proper time, and by these means you will effect a cure.

And now for the reasons why I knew this was not a case of disease of the knee-joint proper,—and you will perceive it had its difficulties. Here was a girl, pale, thin, and weak, confined to her bed for two years with this suppurative disease of the knee, a history of former disease of the elbow-joint with excision, and of whom many would exclaim, "Poor thing! how terribly has that scrofula been preying upon her system! will it ever cease?" and such similar remarks; besides, what

else could be expected from our past education in regard to these matters? She was sent here, as I before said, for excision, but the moment I saw her knee I told my assistant that it did not look like a disease of the joint proper or of necrosis of the femur, as the openings did not present the appearance of those leading to dead bone, and which were first described by the late Dr. Alexander Stevens. "They looked," said he, "like a hen's anus, all pouting out with a circular puckering-string like a sphincter muscle." Sometimes, however, you will have to paint them a little red to make the resemblance more striking. Next, when probing the sinuses, I found where they led to; not by a straight stiff probe, which would puncture in overcoming resistance, but by a flexible one, which would follow the many devious windings of these canals. This examination satisfied me that there was no disease of the bone; and, in order to find that there was no disease of the joint, I firmly pressed all the articulating portions of the joint in every direction without giving her any pain whatever, and also made firm pressure with the thumb and finger over the coronary ligament without eliciting any pain, thus satisfying me that the disease was entirely extra-capsular. Our operation, which laid these sinuses open freely, gave us a fair opportunity of exploring these parts fully, and thereby proved the correctness of our diagnosis.

Case V.—Here is a man whose elbow-joint you all saw me excise last fall. You can now perceive what perfect motion he now possesses. If you will remember, I took off the heads of the radius and ulna, chipping off the olecranon, but leaving that portion to which was attached the triceps muscle, and then sawed off the end of the humerus as far up as the disease extended. By leaving this piece of the olecranon to which the triceps is attached, I have retained for this man, as you perceive, the perfect power of extension, and the patient is now able, as you also observe, to lift this chair with ease.

TRANSLATIONS.

THE TREATMENT OF MALIGNANT PUSTULE WITH CARBOLIC ACID (Dr. Klingelhoef: *Berliner Klin. Wochen.*, 1874, No. 44).—The use of carbolic acid in the treatment of malignant pustule has been advocated in recent times, and Dr. K. has had several opportunities of testing the efficacy of this mode of treatment. He has had, in the course of the last few years, five persons with this affection under his care, all of whom were tanners and contracted the disease in the same tannery in Offenbach.

It is a striking fact that the seat of the primary pustule was not on parts of the body which came into direct contact with the infected hides, but, with the exception of one case, at such points that any direct infection was highly improbable; and this improbability served to render the diagnosis more obscure and difficult.

Two of these cases, which occurred several years ago, were treated by cauterization of the pustule with caustic potash, after which liquor sodæ chlorinatæ was applied locally, and also administered internally. One of these cases, in which the pustule was seated at the angle of the jaw, recovered, while in the other, in which the pustule was on the side of the neck, a fatal result followed within forty-eight hours.

The remaining three cases occurred in later years, and were treated successfully with carbolic acid. Although no definite conclusion can be drawn from the results of the treatment of so few cases, still Dr. K. thinks that in the use of this remedy he has a valuable aid in treating this affection.

The remedy was applied in the same way in all three cases: the pustule was cauterized as deeply as possible with carbolic acid which had been liquefied by heat, after which compresses were applied which had been saturated in a concentrated solution of the same acid, and it was also given inwardly. The solution for local application was of the strength of 1 to 8 of water or linseed oil, and for internal administration a solution of 0.6 to 180 parts was given in tablespoonful doses every two hours.

It has been recently asserted that this disease can be conveyed by contagion to persons who are about the patient; but nothing of this kind was noticed in those cases, although in the last case the circumstances were favorable, since the family was poor, and six children occupied the same room with the patient, and one of them, who suffered from eczema, even slept on the same bed. W. A.

URETHRAL FEVER.—M. Paulet read at a recent meeting of the Société de Chirurgie a report upon a memoir of M. Roux on this subject. M. Roux describes briefly the classic symptoms of this grave complication. He insists upon the analogy which exists between urethral fever and palustral fever. According to M. Roux, the determining cause of urethral fever is as follows. When, after a stricture of the urethra, there is no alteration of the mucous membrane, the sound passes without giving rise to an accident. When, however, the mucous membrane is lacerated or ulcerated, there results an attack of fever if the alkaline and fetid urine is passed through the canal shortly after the operation.

M. Paulet thinks that M. Roux's opinion is too sweeping; all surgeons admitting a previous alteration in the urine. Generally, when the urine is normal, no attack of urethral fever is observed; it is only when the urine is altered, the secretion being slow and incomplete, that accidents follow catheterism.

But is the lesion always seated in the canal? Yes, when there is an old stricture or an alteration of the urethral mucous membrane. But when the urethra is healthy, when the urine is easily passed, may not absorption take place by the vesical mucous membrane? The alkaline state of the urine allows it to dissolve the epithelium and denude the derm of the bladder, and the contact of the sound is sufficient to cause a lesion of the vesical walls.

M. Roux, placing the point of departure for the disease in the urethra, has chosen the name *urethral fever*. M. Paulet, however, prefers the title *urinary*, or *urethro-vesical fever*. M. R. says that on account of the alkalinity of the urine fermentation takes place, and that absorption of the fermentive material gives rise to the fever; that it is a zymotic affection. Carbonate of ammonium is absorbed in too small quantity to be considered a cause of the fever.

In affections of the urethra and bladder, the kidneys are generally attacked. But M. Roux maintains that cases of uræmia are quite different from those of urinary fever. This can hardly be said to be true as regards certain forms of uræmia,—comatose, etc.

The distinction, however, is difficult to make.

To prevent the access of fever, the author advises that the original affection should be treated. Bromide of potassium should be given as a calnative, proper instruments should be employed, and sulphate of quinine and ergot should be administered. After the access of the fever, alcohol and sulphate of quinine may be employed.—*Gazette Hebdomadaire*, No. 51, December 18, 1874. X.

PUNCTURE IN STRANGULATED HERNIA.—At a recent session of the Société de Chirurgie, M. Labbé reported two observations made by M. Ollivier (of Rouen) of strangulated hernia treated by puncture.

A man 64 years of age had an inguinal hernia, strangulated during the last twenty-four hours; taxis under chloroform was unavailing. Returning the next day, forty-eight hours after the occurrence of strangulation, puncture of the tumor was performed. M. Labbé remarks that a patient with strangulated hernia should never be quitted until the hernia is reduced or an operation has been performed. Upon opening the tumor, a small quantity of a brown, serous fluid exuded. The intestine, inflamed and covered with false membranes, was reduced. The patient died eight hours subsequent to the operation. This fact is unfavorable to the operation by puncture of the intestine; and the operation should be performed at an early moment, when the intestinal walls retain their elasticity to a sufficient extent to close spontaneously over the wound made by the trocar.

Another observation concerned a voluminous umbilical hernia in a woman 65 years of age, which had been strangulated for some hours. No chloroform was given, on account of advanced disease of the heart. The tumor was partially transparent. Puncture was made by means of the trocar, resulting in the exit of a wineglassful of serous fluid. Reduction was obtained by means of taxis, and the operation resulted in recovery.

In this case puncture of the sac enabled reduction of the intestinal loop.—*Gaz. Hebdom.*, No. 51, 1874.

THERAPEUTIC NOTES.

NEW METHOD OF ADMINISTERING RAW MEAT.—Raw meat is a very repulsive medicinal agent, under what form soever it be given to invalids. The solid form is by no means advantageous, and its administration is impracticable with young children and convalescents. By M. Yvon's process, a product is obtained which may be administered in either a solid or liquid form. He takes of raw beefsteak, 250 parts; blanched sweet almonds, 75 parts; bitter almonds, 5 parts; white sugar, 80 parts. The almonds are first blanched, and then pounded up with the meat and sugar in a marble mortar, so as to obtain a homogeneous paste. To obtain a nice-looking product, and to retain at the same time the few fibres which may have escaped the action of the pestle, this paste may be reduced to pulp. When it has undergone this process, it is of a pale pink color, and has a very agreeable flavor, not in the least like raw meat. It will keep without change for some time, even in summer, if it be placed in a cool, dry place. If it be desired to give it in a liquid form, it will be enough to dilute a certain quantity of it with water, according to the degree of fluidity required. The emulsion may also be prepared at once, as follows: raw meat, 50 parts; blanched sweet almonds, 15 parts; bitter almonds, 1 part; white sugar, 16 parts, are all pounded in a mortar as in the first formula; the quantity of water needed is added by degrees; and all is then passed through a sieve. Whichever mode of preparation be adopted, the emulsion will keep for at least four-and-twenty hours; and when it separates, at the end of that time, a slight shaking will re-establish the suspension. Some yolks of eggs will make this emulsion more nourishing (*Journal des Connaissances Médicales*). M. Taillier, the head apothecary at the asylum of Quatre-Mares-Saint-Jon, employs the following preparation for the insane patients to whom it is necessary to administer raw meat (*Répertoire de Pharmacie*): grated raw meat, 100 parts; powdered sugar, 40 parts; wine, 20 parts; tincture of cinnamon, 3 parts. The sugar is incorporated with the raw meat in a marble

mortar; and then the wine and tincture are added. A mixture like marmalade is obtained, having an agreeable flavor, and possessing all the requisites of a tonic and revivifying diet. This preparation has many recommendations, though it does not possess all the advantages of the one recommended by M. Yvon.—*British Medical Journal*.

KOUMIS.—The *American Journal of Pharmacy* gives the following directions from an Oriental source:

A certain proportion (one-third) of koumis is poured, together with (two-thirds of) fresh mare's milk, into a clean wooden vessel resembling an ordinary English churn, and there left for from six to eighteen hours, according to the degree of (alcoholic) strength that is required. During this period it is from time to time subjected to a churning process, with the object of keeping up and stimulating the process of fermentation. Herein consists the chief art, and whatever secret there may be in koumis-making is to know the exact amount of churning required; for, although a certain amount is requisite, it must be suspended at the point where curds or butter would be formed. Habit and practice alone teach this to the koumis-maker. After this fermenting process, stimulated by the occasional churning, has lasted a certain time, say six hours, a portion of the contents of the churn is drawn off, and this constitutes the weakest kind of koumis, say koumis of the first degree of strength. The remainder in the churn is subjected to a further period of similar fermentation and churning, say for another six hours, and then the churn is again tapped, and koumis of the second degree of strength is the result. Then another period of, say six hours, of a similar process, for what still remains in the churn, and this, when drawn off, constitutes koumis of the third degree of strength. It will be observed that the difference in the degree of strength of the koumis consists in the different amount of fermentation to which it has been subjected. The strength of the koumis ought to be graduated according to the requirements of different patients; and this is a matter of some importance in the case of invalids. As soon as the koumis is drawn off, it is poured into ordinary quart bottles, made with extra strong necks, corked down and tightly strung; for, containing as it does large quantities of carbonic acid gas, it is subjected to the explosive accidents of all such liquors. Indeed, the inexperienced koumis-drinker, on opening a bottle of koumis for the first time, if he is lucky enough not to lose his eye by the explosion of the cork, will most undoubtedly be soured all over by the frothing liquid.

CRAYONS OF IODOFORM IN THE TREATMENT OF UTERINE MALADIES.—M. Gallard prescribes crayons of iodoform which may be allowed to remain in the cavity of the neck of the uterus, being retained in position by means of a tampon of cotton. These crayons are used with advantage in cases of superficial ulceration of the neck which has invaded the cavity. The following formula is given:

R Iodoform, in very fine powder, 3iiss;
Gum arabic, finely powdered, gr. viiss.

Sufficient mucilage to make into a pilular consistence. Divide into ten cylinders each about one inch long; dry in the air for twenty-four hours. Each crayon contains a little less than a grain of iodoform. These cylinders are hard and resistant; they may be divided into morsels without breaking.

They become disintegrated in the open air, and much more rapidly in the uterine cavity. In order to preserve these crayons, they should be sealed in a dark and air-tight bottle.

IN SEVERE ASTHMA.—Inject five grains of chloral subcutaneously, in twenty minims of water.

PHILADELPHIA
MEDICAL TIMES.
 A WEEKLY JOURNAL OF
 MEDICAL AND SURGICAL SCIENCE.

The Philadelphia Medical Times is an independent journal, devoted to no ends or interests whatever but those common to all who cultivate the science of medicine. Its columns are open to all those who wish to express their views on any subject coming within its legitimate sphere.

We invite contributions, reports of cases, notes and queries, medical news, and whatever may tend to increase the value of our pages.

All communications must bear the name of the sender (whether the name is to be published or not), and should be addressed to Editor Philadelphia Medical Times, care of the Publishers.

PUBLISHED EVERY SATURDAY BY

J. B. LIPPINCOTT & CO.,

715 and 717 Market St., Philadelphia, and 25 Bond St., New York.

SATURDAY, FEBRUARY 6, 1875.

EDITORIAL.

HEIDENBLUT.

THIS young man, our readers may remember, was, after some delay, recently executed for murder. The course pursued by Governor Hartranft in this case has been so eminently just and proper that it deserves to be mentioned in terms of the highest commendation.

Shortly after the trial, Heidenblut's counsel, suspecting that he was not quite sound in mind, requested a gentleman having some experience in mental diseases to examine into his mental condition. After an examination as thorough as could be made under the circumstances, this gentleman came to the conclusion that there was some ground for the suspicion of insanity,—that form of it which occurs in what the French call *épilepsie larvée*. This suspicion, it must be understood, was founded on his own story, which, owing to his dulness of intellect and his inability to speak a word of English, might, without any intention to deceive, have conveyed an impression not strictly correct. The expert, in transmitting to the Governor the minutes of the examination (for every question and answer had been written down), together with a letter giving the impression it had made on his own mind, suggested the propriety of delaying the execution, and, after a while, subjecting the prisoner to the examination of a commission of experts.

The execution was delayed in accordance with this suggestion, and a commission consisting of five eminent physicians—one of whom did not serve—was

appointed to inquire into his mental condition. They failed to find any substantial reason for doubting the prisoner's mental sanity, and the Governor accordingly issued at once the warrant for his execution.

We desire to call attention to the action of Governor Hartranft as peculiarly just and fit; evincing a proper feeling of humanity on his own part, a due respect for the reasonable doubts of others, and a judicious deference to the light of medical knowledge. We hope that the effect of this example will be such that the public will hereafter be spared the spectacle of men of doubtful sanity hurried off to an ignominious fate, the result of their misfortune rather than their fault.

CREMATION appears to be gaining practical favor. The body of the wife of a medical man was recently reduced to ashes semi-publicly in Dresden. The Paris correspondent of the London *Lancet* describes the scene as follows:

"In the midst of Siemens's manufactory had been erected a sort of funereal chamber, profusely ornamented with flowers, and in the centre of which was to be seen the coffin of the deceased. After a short and appropriate allocution from Siemens himself, the clergy having refused to attend, the body was pushed into the oven, and the iron door of the oven closed. A current of air, heated to the utmost degree, was let into the oven, and enveloped the delicate body of the woman, as could be seen through the iron gratings, with waves of fire vibrating distinctly and burning with a crimson light. It was not a thick smoking flame, causing swelling and distention of the body, but a real process of desiccation, extraordinarily rapid, producing evaporation of the chemically combined water, then heating the body, causing it to become red-hot, and afterwards white-hot, and finally to fall to ashes. In all this there was nothing offensive to the smell or hearing. There was nothing in all that was seen through the iron gratings to shock the feelings of the woman's friends, except perhaps the unusual sight of a human body being reduced to ashes. In a short space of time the whole process, during which the liver and lungs seemed especially to resist, was terminated, and yesterday the ashes were gathered with suitable solemnity and confided to an urn."

So long as Europeans are foolish or wicked enough to buy "bogus diplomas," and their governments weak enough to allow their subjects or citizens to practise medicine upon such certificates of merit, so long will American or European scoundrels furnish the desideratum. If there is a demand for any devilish invention, the devil will always furnish manufacturers. The receiver is as bad as the thief.

The trade cannot be stopped except by cutting off the demand, which in this case it would be very easy to do. We notice, therefore, with great satisfaction, that a Mr. Stoker has been sentenced in Scotland to imprisonment for practising medicine upon the authority of two diplomas granting a title of M.D., one from the Livingstone University in America, the other from the Edinburgh University of Chicago, the latter having been granted for a fee of fifty dollars by one Dr. Robertson, without any examination.

MADAME ANDRÉ has received from the examiners of the Montpellier School of Pharmacy their diploma, which qualifies its possessor to practise the art in France.

PROCEEDINGS OF SOCIETIES.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

WEDNESDAY, NOVEMBER 25, 1874.

The President, Dr. WASHINGTON L. ATLEE, in the chair.

DELIVERY AFTER DEATH—LIFE OF A SIX-MONTHS' FŒTUS.

DR. M. O'HARA remarked that he had been engaged to attend a lady in confinement, who had phthisis; the symptoms were advancing quite rapidly when he ceased to attend her. He noticed her death in the *Ledger*, and, on calling, learned that another physician had attended her, and that he had prognosed that she would be carried away, as she was, by sudden hemorrhage. Subsequently, at the request of the clergyman, another physician was called, who opened the uterus, and an eight-months' fœtus with signs of life was baptized. He learned from the physician that the operation was performed an hour and a half or two hours after the death of the mother. The fœtus gasped three times, and was duly baptized by the clergyman. A friend of his states that he was awaiting the death of a woman under similar circumstances, but, being called about forty-five minutes after, he did not think it proper to interfere. The Catholic clergy insist that it is the duty of the physician under such circumstances to open the womb, and give the child a chance for life and baptism, even if forty-eight hours had elapsed. They give Cangiamilla as authority, who, in his *Sacred Embryology*, affirms that in the space of twenty-four years twenty-one children were saved at Montereale, thirteen at Girgenti, and that the Cæsarean operation was performed, under these circumstances, twenty times at Syracuse in the course of eighteen months. Cases of suspended animation at birth are recorded. And all practitioners are familiar with cases in which artificial respiration, cold water, etc., apparently bring about activity in the course of twenty minutes or a half-hour.

Rigaudeau (Meigs's Velpeau, p. 509) relates that he was sent for, two leagues from Douai, to see a woman whose labor had excited great uneasiness; when he arrived she was believed to have been dead for two hours. Instead of opening the abdomen without an examination, he explored the genital organs, found the pelvis well formed, and proceeded to turn and deliver the child by the feet; it was born in a state of apparent death, but with great exertion was brought to life in about two hours. The limbs of the mother pre-

serving their suppleness, he forbade them to bury her until the abdomen should have turned green. After a few hours this woman recovered so completely from her insensibility that she came herself, four years afterwards, to inform Rigaudeau that she was not dead. The *Lex Regia* of Numa Pompilius ordered the physicians of that period to open the bodies of all women who died pregnant, with a view of preserving citizens to the State. A decree of the Senate of Venice, bearing on this matter, 1608 and 1721, ordered severe penalties on those who should operate upon a person supposed to be dead without the same degree of care as if she were actually living. A law of the King of Sicily in 1749 inflicted the penalty of death upon physicians who should omit to perform the Cæsarean operation upon women who had died in the last months of pregnancy. Flajani, Veslingius, and several other authors relate cases similar to that of the Princess of Schwartzenberg, who died at Paris in consequence of a burn, could not be opened until the next day, and the fœtus was found, notwithstanding, to be living. In a case of death-burn, Dr. O'Hara had awaited the moment of death, and, without difficulty, delivered per vaginam a five-months' fœtus. It was thought to have life, and it was baptized. He would think, with Velpeau, "it is very useless, no doubt, to think of preserving the life of a fœtus previous to the end of the eighth month, but among Catholics there is a desire at least to baptize, and the operation should be performed, in fact, if the woman has passed through one-half of the period of pregnancy."

Dr. WASHINGTON L. ATLEE said he had no experience on the subject referred to by Dr. O'Hara. It is well known, however, that after the death of the mother the uterus will force the fœtus into the world; but he had never heard of an instance of the child having been alive under such circumstances. With regard to the viability of the fœtus during different periods of the progress of gestation, and its capacity of maintaining a separate existence, Dr. Atlee mentioned an instance which occurred in his practice in December, 1845. By the closest calculation the period of gestation had not exceeded six months. A very small child was born. It being very flaccid and apparently lifeless, it was rolled carefully in a cloth and laid to one side. After having recovered the placenta and fixed the mother comfortably in bed, he was asked the sex of the child. Unwrapping it, he noticed a slight gasp, which was followed by others. It was now laid in a bed of cotton wadding, and its grandmother took charge of it, feeding it by dropping milk into its mouth from the point of her finger. It was kept in this bed of cotton, and fed in this way, for two weeks, when it was first washed and dressed. At that time it weighed two and a fourth pounds. It continued to live, and is now a beautiful and vigorous lady.

Dr. H. Y. EVANS then read a paper on "Localized Rest in the Treatment of Pulmonary Affections."

Dr. ESHLEMAN remarked that one result of bandaging the chest referred to by Dr. Evans in his valuable paper was not quite clear to his mind.

This was that it "lessened the frequency of respiration." If we limit the capacity of the lungs by placing at rest the intercostal muscles, compensation would seem to require a more frequent movement of the diaphragm.

Dr. WELCH said he had no experience in the treatment of pulmonary affections by rest, as recommended by the author of the paper, but looking at the question from a physiological stand-point he doubted that the lungs could be placed at rest to any considerable degree by the means suggested. The respiratory act, as is well known, is carried on not by the muscles of the thorax alone, but also by the diaphragm. If we

diminish the action of the former, as the paper proposes, then the latter will take on increased action, and in this way compensate for the diminished thoracic respiration. The author of the paper will recollect witnessing an experiment made not long since to show that this is true. The experiment consisted simply in applying a roller bandage tightly around the chest, when, on measurement, it was found that as thoracic respiration diminished, abdominal respiration increased. This proves that it is doubtful whether the means proposed will place the lungs at rest to any appreciable extent. If, however, it were possible to do so, would it not, in the treatment of pleurisy, increase the liability to pleuritic adhesions?

Dr. DUNBARR had tried the plasters on more than one occasion, but, owing to their being freshly or badly made, they had slipped, irritated his patients, and failed. He has since been depending upon a compress, gored to fit the chest, with ties or pins, and pads for seats of pain; the whole supported by broad bands over the shoulders; special pressure being made over seats of pain.

In one case hemorrhage was arrested, cough subdued, and pain relieved in a marked degree. Was yesterday called to a case of hæmoptysis. Patient had long complained of pain in right breast, and had hemorrhage before. To-day we have no hemorrhage, no pain in breast, and patient declares himself comforted and grateful for the bandage.

In answer to the question, How can strapping the breast prevent the irritation of the diseased lung during respiration? the doctor said that different parts of the lung receive air independently, and at successive intervals. In ordinary respiration the upper part of the lung, and that contiguous to the larger bronchi, being more free of access, are first filled, and do the ordinary moving work of respiration, the lower and deeper parts seldom being called into action. Now, if the upper part or any part be diseased and painful on motion, by proper compression the motion will be arrested and the part kept at rest, friction of the diseased surfaces prevented, and the tendency to pain, cough, and hemorrhage lessened, while the object of respiration will be accomplished by bringing into play those portions of the lung usually at rest.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

WEDNESDAY, May 6, 1874.

DR. JAMES H. HUTCHINSON read a paper on *Lymphadenoma*, of which the following is an abstract:

"W. M. L., æt. 19, unmarried; was admitted into the medical wards of the Pennsylvania Hospital, January 26, 1874. On February 1, the following notes of his case were made:

"The patient's mother died of phthisis, after having suffered for many years from enlargement of the cervical glands, but with this exception there seems to be no tendency to hereditary disease in his family. He has always been temperate, and has never had any form of venereal disease, or any serious illness before the present one began, about six weeks before his admission. At that time he complained of a feeling of soreness in the front of the chest, and in the muscles of the shoulders and arms. He did not, however, have actual pain until several days subsequently, when he became aware of a sensation of constriction at the base of the thorax. He also observed that his lower extremities were weak and numb. This symptom increased in severity until he was unable to walk except with assist-

ance. The day prior to his admission he became absolutely paraplegic, and lost control over his bladder and rectum. He has never had any dorsal pain or any pain in the extremities, but has occasionally suffered from twitchings of the muscles. Upon inquiry it is discovered that he had at one time (some years ago) enlargement of the glands on the left side of his neck, but the enlargement of those on the right side, which is now apparent, was not observed until May last. Soon after his illness began he noticed a swelling over the upper bone of the sternum, which has gradually increased in size, until it is now as large as half an orange. It has been from the first tender to the touch.

"Upon examination the patient is found to have complete paralysis of motion and sensation of all the parts of his body below the thorax. He complains also of a feeling of constriction about at the level of the line separating the sensitive from the paralyzed parts, but he has no pain or tenderness along the dorsal vertebræ. There are, moreover, no contractions and no spasmodic twitchings of the muscles, but there is a notable increase of reflex movements. The palsied muscles respond fairly well to an induced current of moderate intensity, but feebly so to the galvanic. On the right side of the neck there is a mass of much enlarged glands, firm to the touch and not tender. Upon closer examination it is possible to trace the outlines of several glands which appear to be loosely bound together. At the inner part of the upper eyelid there is a tumor, due, probably, to an enlargement of a Meibomian gland. In addition to this and to the tumor over the upper part of the sternum, already referred to, there are numerous tumors, varying in size from a millet-seed to a walnut, distributed over the body, especially on the trunk. They are, for the most part, situated beneath the skin, and are hard to the touch; a few, however, project as pedunculated appendages. The axillary and inguinal glands are slightly enlarged, but free from tenderness. No enlarged glands or tumor of any kind can be felt within the abdominal cavity. Neither the spleen nor the liver is enlarged. The patient is very pale and emaciated; his tongue is slightly furred, his appetite is poor, and the nails of his fingers have a decidedly bluish color. The urine contains an excess of the phosphates, but no albumen. Its specific gravity is 1020. His blood, upon being examined microscopically, is found to contain a slight excess of white cells. No disease of his lungs can be detected, but it is impossible to make a satisfactory examination of them in consequence of the pain he suffers when moved. The heart is healthy.

"Feb. 20.—The patient has become very anæmic, and more emaciated than when the last note was made. Reflex movements can still be excited. The small tumors beneath the skin of the trunk, arms, and legs have increased in size, and this is also true of the large one over the sternum, but it is less tender to the touch than before. A few small nodules can be felt beneath the skin of the face; in fact, there is no part of the body where some cannot be detected upon close examination. They are, however, less numerous on the posterior aspect of the body than in front. The feeling of constriction around the body at the base of the thorax still continues, and gives rise to much suffering. The pain is much increased upon movement."

Daily notes taken after this show that the disease progressed steadily to a fatal termination about five months after the manifestation of the first serious symptoms, and a year after the enlargement of the cervical glands. Just before his death his urine became bloody and ammoniacal, but he preserved possession of his intellectual faculties, and was cheerful. Hypodermic injections of morphia were freely given, and gave him much relief. The temperature-record showed a slight tendency to a febrile exacerbation at night.

At the autopsy the tumor over the sternum was found to penetrate the liver, and to be nearly of the same dimensions beneath as above. Twenty tumors, the largest the size of a small filbert, were counted scattered over the surface of the brain, and closely resembling brain-substance in appearance. A tumor was found completely surrounding the bodies of the sixth, seventh, and eighth dorsal vertebrae, and continuous with this through the intercostal spaces were similar growths, occupying the gutters on both sides of the spinous processes. A smaller tumor was found within the canal at the level of the last dorsal vertebra. The lungs contained a large number of tumors, the average size being about that of a large pea. They were seated immediately beneath the surface of the lungs, as well as in the interior. But one tumor was detected taking its origin from the parietal pleura. Heart was normal. Small tumors were scattered over the peritoneum. Mesenteric glands were enlarged and prominent. Liver was healthy. The connective tissue surrounding it held in its meshes numerous small tumors. Microscopic examination of the tumors revealed that they consisted of a fibrous stroma, containing numerous large, rounded, oval, and somewhat angular cells, and arranged like that of a lymph-gland.

The freedom of the liver and spleen from deposits and enlargements, as well as the slight involvement of the axillary glands, were both unusual. The most remarkable feature was the paraplegia, which was complete. The cause of the disease is very doubtful, as in almost every other reported case. An examination of the blood early in the disease showed a slight excess of white corpuscles. No treatment has been shown to have the slightest influence in arresting the course of this disease.

An interesting analysis of fifty-eight cases of lymphadenoma was then given by Dr. Hutchinson, together with a copious bibliography of the subject.

GLEANINGS FROM OUR EXCHANGES.

PARACENTESIS THORACIS (*The British Medical Journal*, Dec. 12, 1874).—Dr. John Richard Wardell summarizes as follows the morbid states and the positive and negative signs demanding the operation of paracentesis thoracis:

1. In all cases in which inspection and the physical signs give evidence of a large quantity of fluid: when there are symptoms of compression of the lung, and there is manifest cardiac displacement.
2. When there are urgent dyspnœa, an irregular pulse, and threatening of orthopnœa.
3. When the affected side is smooth and rounded, and the intercostal spaces are effaced or protrude; when measurement proves bulging; when the dulness in the chest is complete, or demarcated and absolute; when there is abolition of tactile fremitus; when there are bronchophonic voice, tubular breathing, and absence of breath-sound; when the patient can only lie on one side, or in diagonal position; and when there is the Hippocratic sign of succussion.
4. When the exploratory needle proves the fluid to be purulent.
5. If the heart be pushed from its normal situation, and the apex-beat be substernal or beyond the right sternal edge, or if it be thrust towards the left hypochondrium, or if it be lost; when it becomes presumptive that the organ has been driven inwards and backwards; and when on the one side the liver depends abnormally into the abdomen, and when on the other side the relaxed and down-pressed diaphragm so displaces the spleen that its free edge can be felt.

6. When half the thoracic cavity is filled, and a month or so shows no proof of absorption, the longer the delay the less are the chances of expansion.

7. In those exceptional cases of double pleurisy when both cavities become half filled with effusion, and dyspnœa shows the lung-space to be dangerously encroached upon.

8. In pulmonary phthisis, when the accumulation of serous or sero-purulent secretion causes distress, and when the other lung assumes the symptoms of bronchitis or pneumonia, the operation should at once be performed.

9. In mechanical hydrothorax, it may be had recourse to, though with no object to cure, but with merely a view for a time to prolong life and to aid the action of medicinal remedies.

10. In children, whose chest-walls are thin, and in whom the white tissues are more developed and confer greater resiliency to the thoracic parietes, and whenever there are certain evidences of fluid, it should without delay be evacuated.

11. In hydropneumothorax, it may be generally with safety and benefit employed.

12. Pointing externally should never be waited for.

13. Under certain circumstances, repeated tapings are required.

PHYSIOLOGY OF THE NERVOUS SYSTEM (*New York Medical Record*, December 1, 1874).—Dr. Seguin advances the following propositions:

1. Sensation and perception are executed by means of paths which decussate almost horizontally in the spinal axis; the conduction being by the gray matter, not by the white columns of the cord; coarse sensibility with doubtful consciousness has its seat in the pons Varolii; perfect perception and appreciation are possible only with the help of the cerebral mass.

2. Motion is executed through motor impulses, which, starting from the opto-striate bodies (from cortex to cerebrum also?), traverse paths which decussate almost opposite the motor nerves as far down as the lower margin of the medulla oblongata, where the paths for the trunk and limbs decussate in a bundle, to remain, below this point, in that half of the spinal cord whence arise the nerves going to the muscles.

3. Reflex action is the result of a transformation of an irritation from the periphery into nervous force by a nerve-cell, transmitted centrifugally by a second nerve. That all nervous phenomena are of reflex mechanism is not to be too positively denied.

4. Co-ordination is no faculty, but a function of every portion of the motor tract of the spinal axis from the origin of the third cerebral nerve down.

CAMPHORATED PHENOL (*London Medical Record*).—Bufalini asserts that when equal parts of carbolic acid and camphor are dissolved in alcohol, in about twelve or thirteen hours there rises to the surface of the solution a yellowish stratum of oily appearance: it does not mix with the liquid or water, nor is the camphor contained in the alcohol precipitated by water. This compound he calls camphorated phenol, and, after considerable experience, makes the following statement as to its therapeutic employment:

1. Camphorated phenol produces the same effects as carbolic acid, but is less dangerous. It may be used both externally and internally,—e.g., in enteric fever and other infectious disorders.

2. It has the power of modifying unhealthy wounds, and of destroying the parasites which are present in certain diseases, as septicæmia, typhoid forms of fever, etc.

3. The medical use of camphorated phenol is to be preferred to that of carbolic acid, as the former does not present the disadvantages of the latter.

4. Camphorated phenol, when applied to the wounds, does not irritate them, or act as a caustic or disorganizing substance on them; and may be used in large doses without producing symptoms of poisoning.

MISCELLANY.
